Congenital Chagas disease has been associated with pneumonitis; in an autopsy review of 10 congenital cases, pathologic findings have included diffuse pulmonary interstitial edema and endothelial swelling in lung tissues.

Diagnosis in acute Chagas disease may be made by detecting parasites on blood smear. Culture of parasites from specimens is possible using specialized media, although the usefulness of this method is limited because culture may take several weeks.

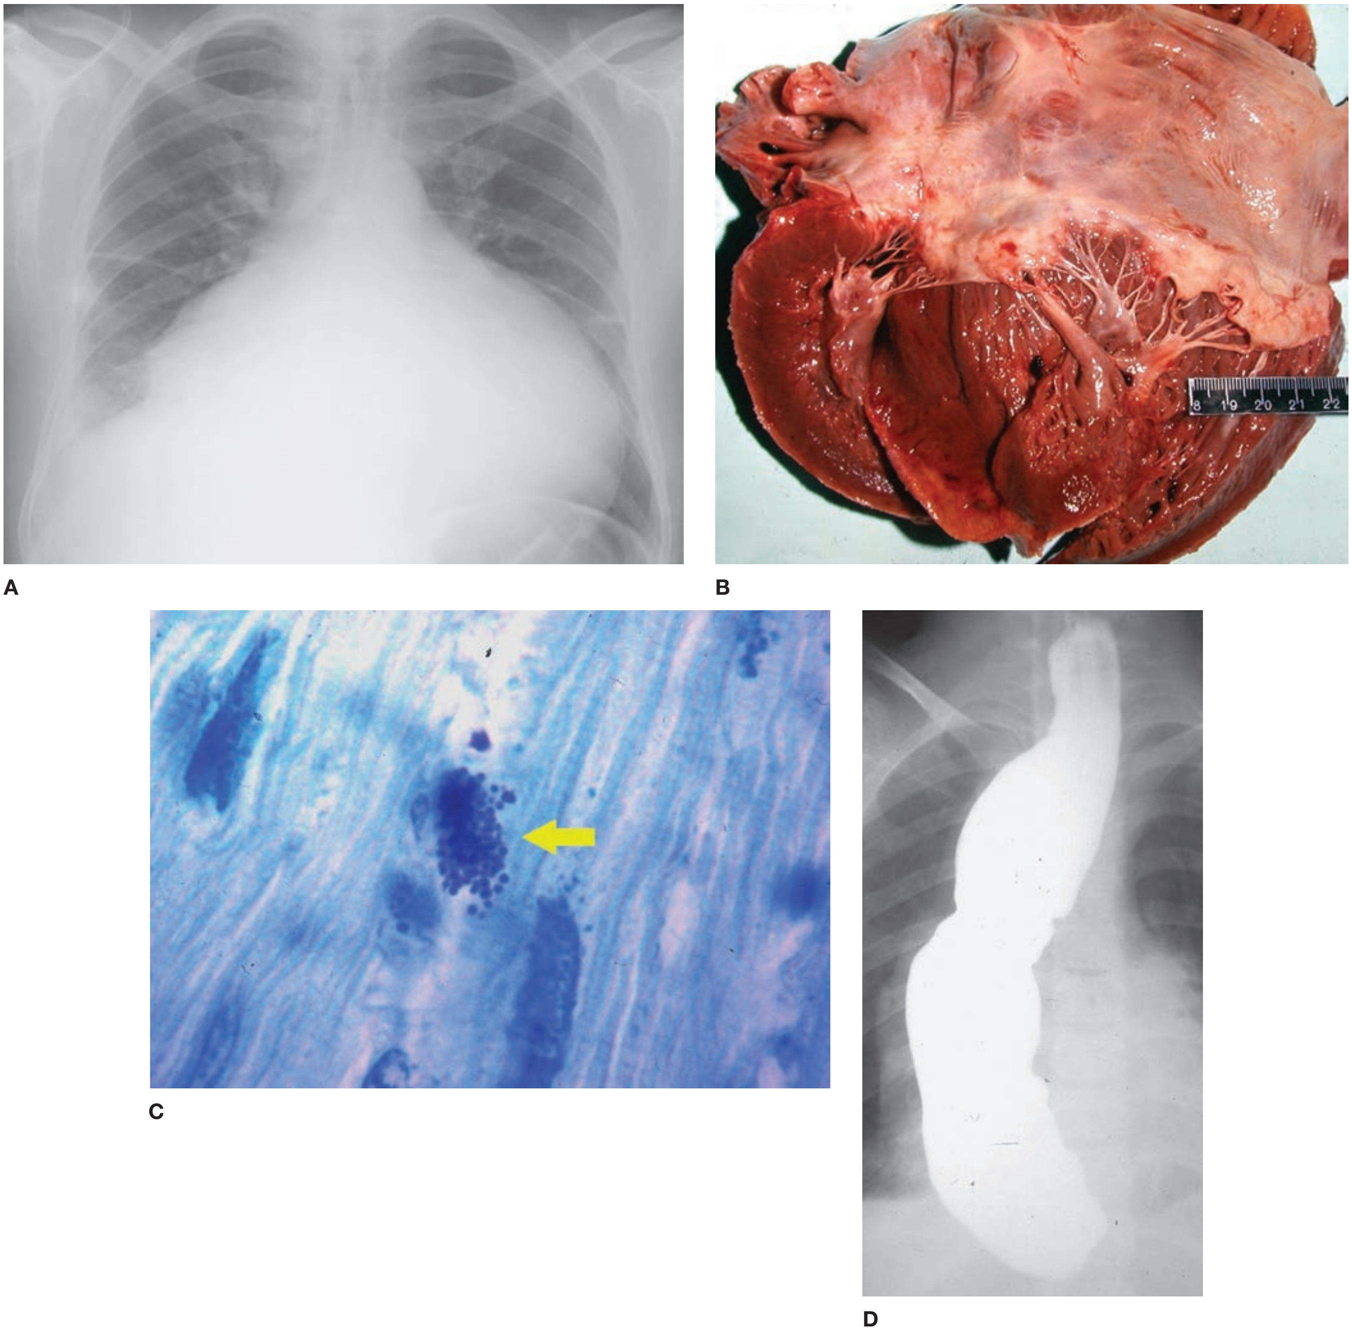

Figure 135-10 Chronic Chagas disease in a 39-year-old man with chronic dilated cardiomyopathy. **A.** Chest radiograph shows global cardiomegaly with pulmonary congestion. **B.** Photograph of the gross specimen demonstrates dilatation of the cardiac chambers with thickening of the ventricular myocardium. Scale is in centimeters. **C.** Low-power photomicrograph (original manifestation, ×10; Giemsa stain) shows *T. cruzi* amastigotes within a myofiber *(arrow)*. **D.** Chagasic achalasia in a 13-year-old girl with Chagas disease. Barium esophagogram shows diffuse and severe dilatation of the esophagus. Histologic analysis demonstrated *T. cruzi* amastigotes within the esophageal wall. *(Reproduced with permission from Martinez S, Restrepo CS, Carrillo JA, et al. Thoracic manifestations of tropical infections: a pictorial review. RadioGraphics. 2005;25(1):135–155.)*

In chronic disease, parasites are not usually visualized. Diagnosis is usually based on serologic analysis, suggestive radiology, PCR analysis, and, more rarely, pathologic examination of tissues. Treatment in acute disease and in patients with immunosuppression is warranted, and nifurtimox and benznidazole are the mainstays of therapy. The utility of treating individuals with established, chronic disease with antiparasitic agents is currently unclear.

African Trypanosomiasis (African Sleeping Sickness)

Trypanosoma brucei gambiense and *Trypanosoma brucei rhodesiense* are the causative agents of African trypanosomiasis (African sleeping sickness). African sleeping sickness is usually transmitted by the bite of an infective tsetse fly. East African trypanosomiasis is caused by *T.b. rhodesiense*. Individuals with East African trypanosomiasis are often acutely ill with fever, lymphadenopathy, headache, and myalgia. Disease may be fulminant, and individuals may develop disseminated intravascular coagulopathy, ARDS, hypotension, and shock. The most common pulmonary manifestations during acute disease are noncardiogenic pulmonary edema and ARDS. West African trypanosomiasis is caused by *T.b. gambiense*. Individuals with West African trypanosomiasis usually do not develop severe disease during the acute stage. Rather, months or years after initial infection, infected individuals present with mental status changes, personality changes, recurrent fever, lymphadenopathy, weight loss, and disorders of circadian rhythm. QTc prolongation can occur.[26]

The most common pulmonary manifestation during late-stage disease is pneumonitis second to recurrent aspirations associated with inanition and altered mentation. Direct pulmonary involvement is not common in West African trypanosomiasis. A single case report describes an African child who presented with severe respiratory symptoms and was later found to have African trypanosomiasis.

LEISHMANIASIS

Leishmaniasis is caused by an intracellular protozoa parasite in the *Leishmania* genus. The *Leishmania* parasites are widely distributed and are usually transmitted through the bite of an infective sand fly. Infection of humans may be asymptomatic or may involve the skin (cutaneous leishmaniasis), the mouth or nose (mucocutaneous leishmaniasis), or be systemic (visceral leishmaniasis). Human infection is most common in South and Central Asia, the Middle East, the Mediterranean, Balkans, North Africa, sub-Saharan Africa, and Central and South America. Specific organisms are often responsible for specific clinical syndromes, although overlap occurs. Disease is often considered as “New World” or “Old World,” based on geographic location. The parasite exists as an intracellular organism (amastigote) in host macrophages, and as an extracellular promastigote in the sandfly gut—being inoculated into the host’s skin during the bite of the fly.

Clinical Features

Cutaneous syndromes may range from localized disease, usually on exposed areas of skin, to widespread cutaneous involvement. In localized disease, painless ulcers develop and most often resolve spontaneously over months. Classically, “Old World” cutaneous leishmaniasis is caused by *L. major*, *L. tropica*, *L. aethiopica*, or *L. infantum*; “New World” cutaneous disease is usually caused by *L. braziliensis* or *L. mexicana* complex organisms. Some New World species are associated with the development of mucocutaneous disease months to years after resolution of the initial skin lesions. Severe destruction and disfiguration of the face with resultant aspiration pneumonitis may occur.

Visceral leishmaniasis is usually caused by *L. donovani*, *L. infantum*, or *L. chagasi*. Individuals with visceral leishmaniasis usually present with fever, hepatosplenomegaly, weight loss, pancytopenia, and hypergammaglobulinemia. Lymphadenopathy is commonly present. Gastrointestinal symptoms are common in advanced disease, and individuals with untreated visceral leishmaniasis develop a wasting syndrome. Pneumonia and tuberculosis may be the cause of death.

Pulmonary Disease

Pulmonary involvement from leishmaniasis in immunocompetent hosts is rare, but interstitial pneumonitis has been reported. However, immunosuppressed patients, particularly those with HIV infection, are at increased risk of atypical disease. In areas surrounding the Mediterranean, where seroprevalence for *L. infantum* in young adults may be as high as 30%, an increase in the incidence of HIV infection has caused an increase in the number of advanced cases of visceral leishmaniasis—a result either of new infections or reactivation of old infections. Patients with leishmaniasis and HIV infection may present with cough, dyspnea, hemoptysis, granulomatous mediastinal lymphadenopathy, solitary pulmonary nodules, or pleural effusions. Advanced visceral leishmaniasis may be complicated by suprainfecting pneumonia even in immunocompetent hosts.[27]

Treatment of leishmaniasis depends on type of disease (cutaneous vs. mucocutaneous vs. visceral), infecting species, parasite resistance patterns, severity of disease, and status of the host. Therapeutic options include liposomal preparations of amphotericin, amphotericin B, pentavalent antimony (sodium antimonylgluconate or N-methylglucamine antimonate), pentamidine, and miltefosine.[28]

CILIATE INFECTIONS: *BALANTIDIUM COLI*

Balantidium coli is the only ciliated protozoa that infects humans. Infection of humans usually occurs in individuals with contact with pigs, and human disease usually manifests as an infectious colitis very similar to amebiasis. Rare cases of pulmonary infection have been reported in humans: in a leukemic patient who presented with pulmonary lesions, in a 71-year-old woman with anal cancer and pneumonia, and in a patient with chronic colitis and an intrapulmonary mass.[29,30]

Diagnosis is usually made through histologic examination of tissue samples. Treatment with tetracycline, metronidazole, or iodoquinol is usually effective.

FLAGELLATES

Two flagellates are discussed briefly below: *Trichomonas* species and *Giardia lamblia*.

Trichomonas Sp.

Trichomonads are flagellated protozoa. Pulmonary disease has been attributed most commonly to *Trichomonas tenax*, an organism that is most often considered a commensal in the human oropharynx, especially in individuals with poor oral hygiene. In one study of symptomatic patients, prevalence of *T. tenax* by PCR among 100 immunocompromised and 100 patients with chronic pulmonary disease was 10%.[30]

Diagnosis is most often made by examination of a wet mount of sputum or bronchoalveolar lavage specimen. Chronic purulent, necrotic pulmonary disease, or pleural involvement has been described, often thought to be a result of aspiration.[31] Affected individuals have responded to metronidazole therapy.

Giardia Lamblia

Giardia lamblia is a pathogenic intestinal flagellate of humans. In humans, it usually causes chronic diarrhea and malabsorption. There is one case report of uncertain significance of recovery of *G. lamblia* trophozoites from bronchoalveolar lavage fluid.

MICROSPORIDIOSIS

Microsporidia is the name given to a group of spore-forming obligate intracellular organisms from the phylum *Microsporidia*. These organisms have been variously considered with the protozoa and fungi. More than 1400 microsporidia species occur worldwide, but the most common human pathogens are *Enterocytozoon*, *Encephalitozoon*, *Nosema*, *Pleistophora*, and *Septata* spp.

The microsporidia spore is the infective form of the organism, and when ingested or inhaled, it extends a polar tubule that infects the host cell. Within the host cell, replication occurs and more spores are formed. When spores sufficiently fill the cell, the cell membrane ruptures and spores are released; they may then proceed to infect nearby cells, or be passed into the environment in stool, urine, or respiratory secretions.

Most clinical cases of microsporidiosis in humans occur in immunocompromised hosts. In immunocompetent patients, infection with *Enterocytozoon bieneusi* can be asymptomatic or may cause acute and very rarely chronic diarrhea. In patients with HIV infection, symptomatic microsporidiosis tends to occur in advanced disease, such as when CD4 cell counts are less than 100 cells/mm^3. *E. bieneusi* and some species of *Encephalitozoon* (*E. hellem*, *E. cuniculi*, and *E. intestinalis*) have come to be recognized as major causes of diarrheal enteritis and disseminated infection in patients with AIDS. Disseminated disease caused by *Trachipleistophora* also has been described. Microsporidial species have been associated with disseminated disease including biliary tract disease, sinusitis, myositis, respiratory infection, and keratoconjunctivitis.

Pulmonary Disease

Microsporidial disease with specific pulmonary involvement has been described in cases of patients with HIV infection, and in individuals who have undergone bone marrow or organ transplantation (Fig. 135-11).[32]

Pulmonary disease usually occurs in the setting of concomitant intestinal infection. In one retrospective review of 42 patients with HIV and microsporidial infection, 24% had respiratory symptoms, and 4 of 6 patients who had specimens examined had sputum or bronchoalveolar lavage positive for microsporidia.[33]

Diagnosis

Diagnosis of microsporidiosis is based on identification of organisms in specimens of tissue or stool. Modified trichrome staining allows detection of organisms on light microscopy, but electron microscopy is currently the definitive diagnostic method. Tissue culture, serologic assays, and PCR testing are used in research settings but are not yet commercially available.

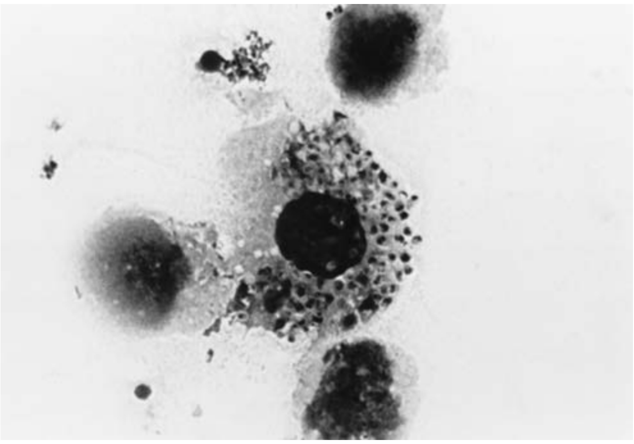

Figure 135-11 Pulmonary microsporidiosis. Tiny organisms (~1 μm) within a pulmonary macrophage obtained via bronchoalveolar lavage (Giemsa–Wright stain, ×1000). *(Reproduced with permission from Dr. C. Wanke.)*

Treatment

Albendazole has activity against *Encephalitozoon* species but is only partially effective against *E. bieneusi*. *E. bieneusi* should be treated with fumagillin. In immunocompromised individuals, treatment is directed at enhancing the immune status of the patient—that is, antiretroviral therapy in patients with HIV infection, and decreased immunosuppression in transplant recipients. Duration of therapy depends on the severity of illness.

CHAPTER 136

Helminthic Diseases of the Lung

Ricardo M. La Hoz
James B. Cutrell

INTRODUCTION

Parasitic worms, also known as helminths, are a leading cause of global morbidity and mortality, particularly in low-income and resource constrained regions. More than 1 billion people in developing areas of sub-Saharan Africa, Asia, and the Americas are infected with one or more helminth species.[1] The helminths causing human disease include the nematodes (roundworms) and the platyhelminths (flatworms). The platyhelminths are further subdivided into the cestodes (tapeworms) and the trematodes (schistosomes and other flukes).

Individuals with helminthic infections of the lung often seek medical advice due to cough, chest pain, or shortness of breath. They may have unexplained laboratory abnormalities (eosinophilia) or imaging abnormalities (nodule or a mass). In nonendemic areas, they pose a diagnostic challenge given their overlap with other clinical syndromes. A thorough history that includes travel to or long-term residency in endemic areas as well as environmental or dietary exposure are key to the diagnosis. Helminthic infections of the lung may be categorized by their principal clinical presentation (Fig. 136-1). Once the diagnosis is suspected, clinicians must pursue appropriate diagnostic testing to direct therapeutic intervention (Table 136-1). Herein we outline a diagnostic approach to suspected pulmonary disease caused by helminths, followed by review of the most common helminths affecting the respiratory system.

APPROACH TO DIAGNOSIS OF SUSPECTED PULMONARY HELMINTHIC DISEASE

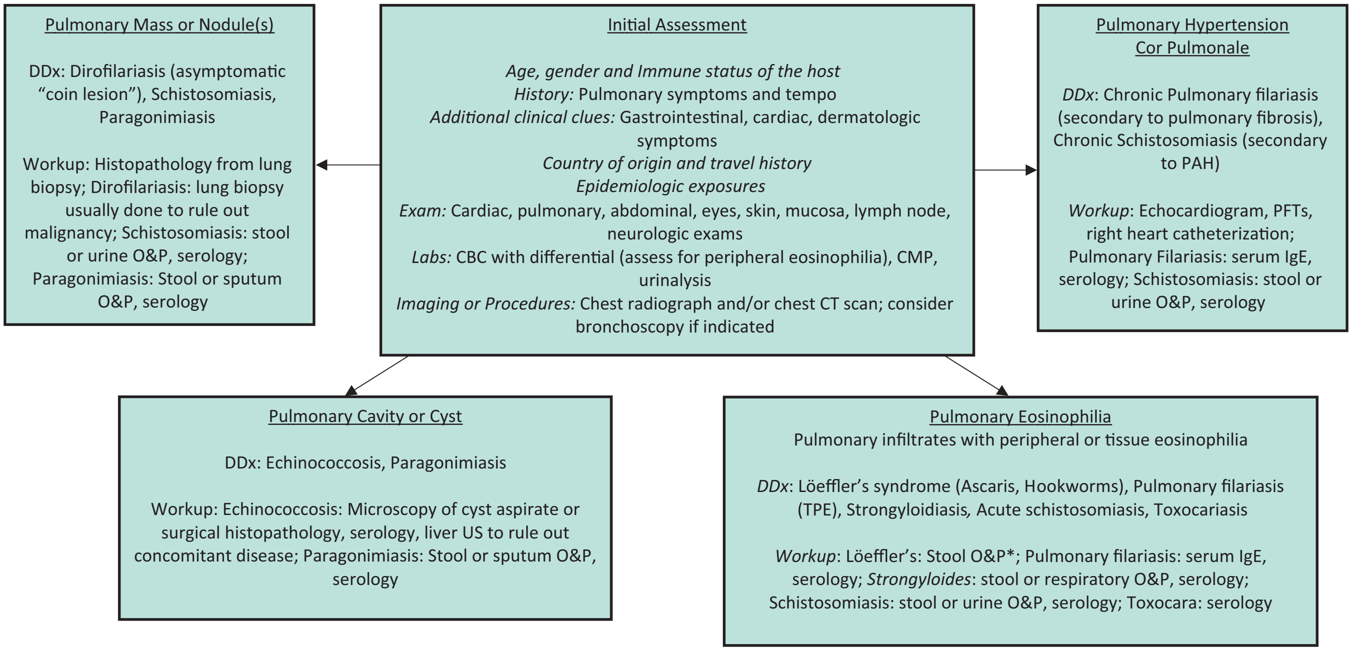
Given their nonspecific symptoms and overlap with other infectious and non-infectious etiologies, helminthic pulmonary infections require a high index of suspicion to prompt their diagnosis. A comprehensive history should characterize the cardiopulmonary symptoms, including their tempo and chronicity, and a detailed review of systems should evaluate for other concomitant sites of involvement such as the skin, eyes and gastrointestinal (GI) tract. Special attention to the immunologic status of the patient, particularly cellular immune defects and any immune-modifying therapies, such as corticosteroid use, may alert physicians to risk factors for disseminated disease or obscure typical diagnostic clues such as peripheral eosinophilia. A thorough social history should focus on the patient's country of origin, as well as recent and remote travel to endemic geographic regions and address any important epidemiologic clues, including dietary, occupational, recreational, animal, or insect vector exposures. Armed with this information, a targeted physical examination and initial laboratory and radiographic evaluation can assist in categorizing a patient's clinical syndrome and directing a focused diagnostic workup for potential helminth pathogens.

SPECIFIC PARASITES

In the sections that follow, we discuss each of the most commonly encountered parasites that affect the lung.

■ Ascariasis

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of ascariasis.



Initial Assessment

Age, gender and Immune status of the host
History: Pulmonary symptoms and tempo
Additional clinical clues: Gastrointestinal, cardiac, dermatologic symptoms
Country of origin and travel history
Epidemiologic exposures
Exam: Cardiac, pulmonary, abdominal, eyes, skin, mucosa, lymph node, neurologic exams
Labs: CBC with differential (assess for peripheral eosinophilia), CMP, urinalysis
Imaging or Procedures: Chest radiograph and/or chest CT scan; consider bronchoscopy if indicated

Pulmonary Mass or Nodule(s)

DDx: Dirofilariasis (asymptomatic "coin lesion"), Schistosomiasis, Paragonimiasis

Workup: Histopathology from lung biopsy; Dirofilariasis: lung biopsy usually done to rule out malignancy; Schistosomiasis: stool or urine O&P, serology; Paragonimiasis: Stool or sputum O&P, serology

Pulmonary Hypertension
Cor Pulmonale

DDx: Chronic Pulmonary filariasis (secondary to pulmonary fibrosis), Chronic Schistosomiasis (secondary to PAH)

Workup: Echocardiogram, PFTs, right heart catheterization; Pulmonary Filariasis: serum IgE, serology; Schistosomiasis: stool or urine O&P, serology

Pulmonary Cavity or Cyst

DDx: Echinococcosis, Paragonimiasis

Workup: Echinococcosis: Microscopy of cyst aspirate or surgical histopathology, serology, liver US to rule out concomitant disease; Paragonimiasis: Stool or sputum O&P, serology

Pulmonary Eosinophilia
Pulmonary infiltrates with peripheral or tissue eosinophilia

DDx: Löeffler's syndrome (Ascaris, Hookworms), Pulmonary filariasis (TPE), Strongyloidiasis, Acute schistosomiasis, Toxocariasis

Workup: Löeffler's: Stool O&P*; Pulmonary filariasis: serum IgE, serology; *Strongyloides*: stool or respiratory O&P, serology; Schistosomiasis: stool or urine O&P, serology; Toxocara: serology

**For Ascariasis and hookworms stool microscopy should be ordered 4 to 8 weeks after onset of pulmonary symptoms.*
Abbreviations: CBC, Complete blood count; CMP, Comprehensive metabolic panel; CT, Computed tomography; DDx, differential diagnosis; O&P, microscopy for ova and parasites; PAH, pulmonary arterial hypertension; PFTs, pulmonary function tests; TPE, tropical pulmonary eosinophilia; US, ultrasound.

Figure 136-1 Approach to the diagnosis of suspected pulmonary helminthic diseases.

TABLE 136-1 Treatments for Helminthic Pulmonary Diseases

Parasite	Therapies	Comments
Ascaris lumbricoides	Preferred: albendazole 400 mg orally as a single dose Alternate: mebendazole 500 mg orally as a single dose or 100 mg twice daily for three days	Antihelminthic treatment is only effective against adult worms in the intestinal phase.
Ancylostoma duodenale *Necator americanus*	Preferred: albendazole 400 mg orally as a single dose Alternate: mebendazole 500 mg orally as a single dose or 100 mg twice daily for three days	Antihelminthic treatment is only effective against adult worms in the intestinal phase.
Strongyloides stercoralis	A single dose of ivermectin (200 µg/kg orally) for patients with uncomplicated infection. Oral or parenteral formulations of ivermectin alone or in combination with albendazole have been used for patients with hyperinfection syndrome or disseminated disease.	Ivermectin is only effective against the intestinal stages of the parasite.
Wuchereria bancrofti *Brugia malayi*	Diethylcarbamazine (6 mg/kg divided in three daily doses for 21 days)	Corticosteroids have been used as adjunctive therapy, but clinical trials are lacking to define dose and duration.
Toxocara canis *Toxocara cati*	Visceral larva migrans: albendazole 400 mg orally twice daily for 5 days Ocular larva migrans: albendazole 400 mg orally twice daily for 14 days	Corticosteroids are recommended for ocular disease or severe visceral disease.
Echinococcus granulosus	The mainstay of treatment for pulmonary hydatid cyst is surgery. Albendazole 400 mg orally twice daily for 3 to 6 months is recommended for small cysts or when surgery is not feasible.	Use of albendazole postoperatively may be considered, but guidelines do not recommend treatment preoperatively for large pulmonary cysts.
Schistosoma haematobium *S. mansoni* *S. intercalatum*	Praziquantel 40 mg/kg orally in one or two divided doses for 1 day	Praziquantel prevents further oviposition of adult worms.
Schistosoma japonicum *S. mekongi*	Praziquantel 60 mg/kg orally in two divided doses for 1 day	Praziquantel prevents further oviposition of adult worms.
Paragonimus westermani, *P. kellicotti*	Preferred: praziquantel 25 mg/kg orally three times a day for 2 to 3 days Alternative: triclabendazole 5 mg/kg orally per day for 3 days or 20 mg/kg orally in two divided doses for 1 day	Corticosteroids should be given if concomitant central nervous system disease is present.

Etiology

Infection due to *Ascaris lumbricoides* occurs worldwide. Most individuals with ascariasis live in Asia, Africa, and South America.[2] People living in, travelling to, or coming from areas with poor sanitation are at higher risk for infection. This parasite most commonly infects children and adolescents, with decreasing prevalence in those over 15 years of age.[3] *Ascaris* also affects vulnerable populations in high-income countries. For example, the southeastern United States (US) has historically had the highest burden of *Ascaris*.[4]

Human ascariasis occurs by fecal-oral transmission when embryonated eggs found in the environment are ingested. The eggs hatch in the gastrointestinal (GI) tract, producing larvae that penetrate the enteric mucosa and subsequently gain access to the venous system. They eventually reach the lung via the right side of the heart and migrate to the alveoli through the pulmonary capillaries. Once in the alveoli, they ascend the bronchial tree and are eventually swallowed back into the GI tract where they become adults.

Pathogenesis and Pathology

In patients without prior *Ascaris* exposure, a type-1 hypersensitivity reaction, known as Löeffler's Syndrome, occurs when the larval stage passes through the lung parenchyma.[5] On pathology, portions of larvae are seen in the pulmonary parenchyma, surrounded by a patchy infiltrate of neutrophils and eosinophils.

The immune response to *A. lumbricoides* infection is polarized to a T-helper cell type 2 (Th2) response, characterized by high levels of interleukin (IL)-4, IL-5, IL-13, immunoglobulin E (IgE) as well as tissue eosinophilia and mastocytosis. This organized response stimulates the eosinophil-mediated destruction of migrating larvae and production of IgE against worm antigens. Indirect evidence of the importance of the Th2 response is provided by studies demonstrating an association between a weak Th2 response and susceptibility to reinfection.[6–8] *A. lumbricoides* also stimulates the production of IL-10. Its primary effect is to protect the host from the inflammatory response, but it may also allow the survival of the helminth.[7]

Clinical Manifestations

The symptoms of ascariasis depend on the phase of the disease. In the migratory phase, pulmonary symptoms predominate. Pulmonary ascariasis, the most common cause of Löeffler's syndrome. It predominantly occurs in individuals without prior *Ascaris* exposure and thus rare among people in endemic areas.[5] A study including 13,000 patients in Colombia, where prevalence ranges from 25% to 90%, found only 4 cases of Löeffler's syndrome.[9] The symptoms of cough, dyspnea, chest pain, bronchospasm and hemoptysis begin 1 to 2 weeks after the ingestion of eggs as the larvae migrate through the lungs and last for 5 to 10 days. In addition to the pulmonary manifestations during the migratory phase, some patients may also present with urticaria or peripheral eosinophilia. Analysis of sputum characteristically demonstrates eosinophils and Charcot-Leyden crystals.[10] Chest radiography may show oval or round infiltrates, while computed tomography (CT) of the chest demonstrates pulmonary nodules.[11–13] Chronic intestinal infection with the adult worm is usually either asymptomatic or associated with mild abdominal discomfort, lack of appetite, or changes in bowel habits.

Diagnosis

After ingestion of embryonated eggs, 40 days are required for the larvae to migrate and reach the intestine before maturing to an adult worm capable of producing eggs that can be detected in stool. Thus, although the diagnosis of the migratory phase of *Ascaris* can be suspected based on epidemiological risk factors and clinical presentation, its confirmation is often delayed for weeks. The chronic *Ascaris* intestinal phase is established by identifying *Ascaris* eggs in stool via microscopy. Methods for detection include Kato-Katz and FLOTAC techniques.[14–16] The former is recommended by the World Health Organization (WHO) due to its simplicity and low cost, making it the most commonly used technique. The drawback is that it is labor intensive. The FLOTAC technique is more sensitive but requires a centrifuge that may not be available in some settings.[16] In addition, polymerase chain reaction (PCR) has better diagnostic performance compared to microscopy.[17]

Treatment

Because the migratory phase of ascariasis is self-limited, specific therapy is usually not required. Prednisone use has been described in case series for those with severe disease.[18] Antihelminthic medication is reserved for those with eggs detectable in the stool, as the drugs are only active against the adult worm. The mainstay of treatment for chronic intestinal ascariasis in those older than 12 years of age are the benzimidazoles. Albendazole (400 mg orally as a single dose) or mebendazole (500 mg orally as a single dose or 100 mg orally twice daily for three days) achieve high cure rates with excellent safety profiles.[19–21]

■ *Ancylostoma duodenale* and *Necator americanus*

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of the hookworms, *Ancylostoma duodenale* and *Necator americanus.*

Etiology

Ancylostoma duodenale and *Necator americanus* are the primary hookworms that cause infection in humans. The term hookworm refers to attachment of the buccal cutting plates found in the mouth of these parasites to the intestinal mucosa of the host. Globally, approximately 450 million people are infected with hookworms.[22] *N. americanus* is the most common species, with predominance in sub-Saharan Africa, Southeast Asia, and the Americas. In contrast, *A. duodenale* has endemic foci in India, Pakistan and the Mediterranean region.[23] While *Ascaris* is a helminth affecting children, hookworms predominantly affect adults.[24] In the southern US, infection with *N. americanus* occurs in areas of extreme poverty.[25]

The predominant route of hookworm acquisition is through dermal penetration by the free-living larvae in the soil while walking barefoot. Once the larvae gain access to the venous system, they travel to the right heart and pulmonary circulation. From the pulmonary capillaries, they migrate to the alveoli, ascend through the bronchial tree, and are eventually swallowed. In the intestine, the larvae molt and develop to the adult worm.[26] *A. duodenale* can also be acquired orally, resulting in Wakana Disease, characterized by GI disturbances, cough, laryngeal irrigation and eosinophilia.[27]

Pathogenesis and Pathology

N. americanus and *A. duodenale* may cause a type 1 hypersensitivity reaction during the migratory phase in the lungs (Löeffler Syndrome). The adult worms use their buccal cutting plates to attach to the intestinal mucosa. Hookworms secrete factors Xa, XIa, and VIIa-tissue factor inhibitors that augment blood loss.[28] Intestinal hookworm infection is associated with a Th2 response (elevated IgE, IL-5 and eosinophilia).[29,30] In contrast with other helminth infections, exposure is not associated with resistance to infection due to the development of host tolerance.[31,32]

Clinical Manifestations

Although commonly asymptomatic, clinical manifestations of hookworm infection reflect different phases of the parasite life cycle. Penetration of the skin results in "ground itch," a pruritic erythematous or maculopapular rash which slowly migrates (1–2 cm/day) from common sites of entry on the hands and feet and lasts 2 weeks.[23,33] About 10 days after entering the skin and migrating through the venous system, the larvae reach the lung. Symptoms during this phase are less likely to occur with hookworms than *Ascaris*. As with Löeffler's syndrome caused by ascariasis, cough, chest discomfort, and wheezing are the predominant symptoms and can be accompanied by eosinophilia and pulmonary infiltrates. While the symptoms caused by *Ascaris* in this phase only last 5 to 10 days, they can last up to 30 days with hookworms.[34] The intestinal phase is characterized by abdominal pain, diarrhea, and chronic GI blood loss leading to severe microcytic anemia and its associated complications.

Diagnosis

Diagnosis is established by identifying eggs in stool. Morphologically, the eggs of *N. americanus* and *A. duodenale* are indistinguishable. In the case of *N. americanus*, eggs can be identified in the stool 8 weeks after dermal entry while it can take up to 38 weeks for *A. duodenale*. Thus, stool microscopic examination is unreliable to establish the diagnosis of "ground itch" and Löeffler's syndrome. The Kato-Katz and McMaster's techniques are most commonly used to diagnose the intestinal phase.[35,36] PCR based diagnostics are species specific and have superior sensitivity compared to microscopy.[37]

Treatment

Since antihelminthic treatment is only effective against the adult worm, it is not effective for hookworm-related Löeffler's Syndrome. Treatment is not usually required during this phase although corticosteroids have been used in severe cases. For intestinal infection, Albendazole (400 mg orally as a single dose) has the highest cure rate while mebendazole (500 mg orally as a single dose or 100 mg orally twice daily for three days) is an alternative.[20,21,38] Iron replacement is recommended for those with anemia.

■ Strongyloidiasis

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of strongyloidiasis.

Etiology

Strongyloidiasis affects 370 million people worldwide.[39] The causative parasite, *Strongyloides stercoralis*, is endemic throughout the tropics and subtropics with Africa, Asia, and Latin America being disproportionately affected.[40] In the US, strongyloidiasis is endemic to the Appalachian region.[4,41,42]

S. stercoralis can complete its life cycle both in the environment and in the human host. The primary reservoir of the parasite is soil contaminated with human feces. The filariform larvae penetrate the skin, gain access to the venous system, migrate to the lung, enter the alveoli, ascend the bronchial tree, and then are swallowed. In the intestine, the larvae molt to adult worms. Adult females reproduce sexually and asexually producing eggs that become rhabditiform larvae, which are then eliminated in stool. *Strongyloides* has an auto-infective cycle through which the rhabditiform larvae molt into filariform larvae that can penetrate the intestinal mucosa or perianal skin, re-initiating the cycle. This auto-infective cycle is accelerated in immunosuppressed hosts and is the basis for long-term persistent infections and the severe manifestations seen in those that are immunocompromised.[43]

Pathogenesis and Pathology

The small size of the *Strongyloides* larvae has been linked to the few symptoms observed during lung migration.[44] In the immunocompetent host, *Strongyloides* induces a Th2 response where IL-4 and IL-5 predominate.[45] Patients co-infected with human T-lymphotropic virus-1 (HTLV-1) and other immunocompromised hosts infected with *Strongyloides* have a Th1 skewed response.[46] This coinfection has been linked to lack of parasite control, increased risk of hyperinfection syndrome and disseminated disease, and a lack of eosinophilia in those with severe manifestations.[47]

Clinical Manifestations

The symptoms are dependent on the phase of infection. Edema or urticaria may occur at the site of inoculation. Symptoms during migration through the lung are mild and uncommon[34] while chronic intestinal infections are asymptomatic or have mild nausea, abdominal pain and diarrhea. The auto-infective cycle can cause the following manifestations: *larva currens*, hyperinfection syndrome, and disseminated disease. *Larva currens* occurs when the rhabditiform larvae migrate through the subcutaneous perianal, buttocks, and thighs, creating an urticarial band which migrates 5 to 15 cm per hour.[33]

Hyperinfection syndrome is characterized by an accelerated proliferation of rhabditiform larvae in the intestine that migrate through the intestinal mucosa, travel to the lungs and back to the intestine. In the hyperinfection syndrome, the parasite is restricted to the GI and pulmonary systems. The GI symptoms include anorexia, nausea, vomiting, abdominal pain, diarrhea, ileus, obstruction, and GI bleeding. The pulmonary symptoms include wheezing, dyspnea, hemoptysis, and acute respiratory distress syndrome. Frequent complications of hyperinfection syndrome include septic shock (50%) and bacteremia (40%) caused by translocation of intestinal flora carried by migrating larvae. Disseminated disease consists of hyperinfection syndrome coupled with spread of larvae to other organs. The mortality rate approaches 50% in hyperinfection syndrome and 70% in disseminated infection.[48–50]

Diagnosis

The diagnosis of strongyloidiasis is made by serological methods or by detecting larvae in a clinical specimen (Fig. 136-2). Serological methods are commonly used to diagnose chronic uncomplicated intestinal strongyloidiasis.[51] The sensitivity and specificity of serologies are 75–95% and 95–100%, respectively.[52] False positive results occur with other helminths while false negatives occur in immunocompromised hosts, particularly in those with hyperinfection syndrome or disseminated disease.[53,54]

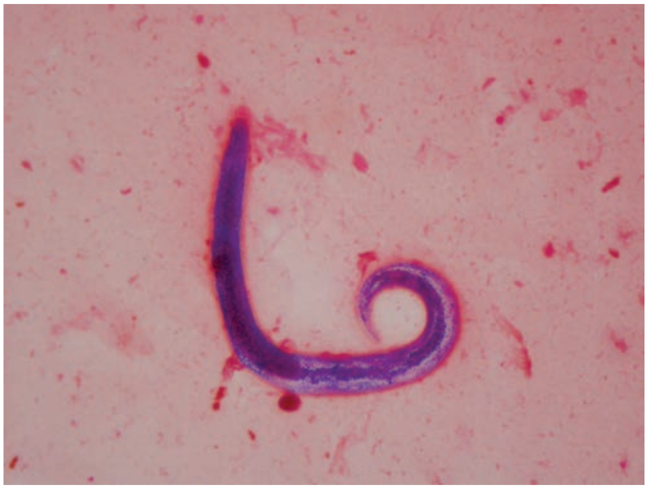


Figure 136-2 Gram stain of a bronchial wash demonstrating a rhabditiform larva of *Strongyloides* at 400× magnification. *(Reproduced with permission from Dr. Dominick Cavuoti.)*

Patients with chronic uncomplicated intestinal strongyloidiasis have a low parasitic burden with intermittent excretion of larvae. Thus, a single stool sample lacks adequate sensitivity, which can be increased with multiple samples.[43,55] The Agar Plate method is the most commonly used method to identify stool larvae and has the highest sensitivity.[42] In hyperinfection or disseminated disease, larvae can be found in respiratory secretions, cerebrospinal fluid, peritoneal and pleural fluid. Affected organs should be sampled to increase the diagnostic yield. Although patients with uncomplicated infection may have eosinophilia, those with hyperinfection syndrome or disseminated disease usually (70–100%) have normal eosinophil counts.[48,50,56,57] Patients diagnosed with *Strongyloides* should be screened for HTLV-1 since co-infection is associated with a high risk of relapse.[58,59] Although not widely available, PCR tests have been developed to detect *Strongyloides* in stool samples.[51] Different techniques have been used and the performance has varied.[56,60]

Treatment

Ivermectin is the treatment of choice for strongyloidiasis and can be administered via oral, rectal, and subcutaneous routes.[61–64] Ivermectin is only effective against the intestinal stages of the parasite.[65,66] Albendazole is considered second-line therapy based on a meta-analysis demonstrating that ivermectin is more effective than albendazole.[61,67–69] A single dose of ivermectin (200 μg/kg orally) was compared to multiple doses of ivermectin (200 μg/kg given on days 1, 2, 15, and 16), demonstrating similar efficacy and better tolerability with a single dose regimen.[70] Since immunocompromised hosts were excluded from the study, some experts still advocate for a multi-dose regimen in this population. Patients from west and central Africa should be screened for microfilarial disease with a blood smear because treatment with ivermectin in this scenario may trigger the Mazzotti reaction within 7 days.[71]

Limited data exist to guide the optimal management of *Strongyloides* hyperinfection syndrome and disseminated disease. In addition to antihelminthic therapy and supportive care, broad spectrum antimicrobials are also recommended given the high rate of concomitant bacterial sepsis. Ivermectin (200 mcg/kg orally daily) for two weeks after the last positive stool sample is recommended to cover for a complete autoinfection cycle. Combination therapy with albendazole has been used for those with hyperinfection syndrome and disseminated disease.[72] Subcutaneous ivermectin (200 mcg/kg/daily) is favored over rectal ivermectin for those unable to tolerate oral therapy.[73–76] In the US, use of the veterinary subcutaneous formulation requires an emergency investigational new drug application (eIND).[77]

■ Pulmonary Filariasis

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of filariasis.

Etiology

Pulmonary filariasis, referred to as tropical pulmonary eosinophilia (TPE), is a distinct clinical syndrome due to pulmonary immune hyperreactivity directed against the filarial nematodes *Wuchereria bancrofti* and *Brugia malayi*. Transmitted by mosquito vectors, filarial infections are endemic in the tropics and subtropics, including the Indian subcontinent, southeast Asia, South America, and Africa. While more than 120 million people are infected with lymphatic filariasis globally, fewer than 1% manifest pulmonary symptoms of

TPE.[78] For unclear reasons, most reported cases of TPE occur in adolescents or young adults from India with a strong male predilection.[79]

Following mosquito bite injection of the infective third-stage larvae, the nematodes develop into the adult male and female worms (macrofilaria) which take up residence in the lymphatics and lymph nodes. From here, microfilariae are released into the peripheral circulation to be picked up by mosquito vectors completing the life cycle. In lymphatic filariasis, microfilariae levels in the blood can peak at specific times of day (periodicity), which may be important diagnostically. However, in TPE, microfilariae are commonly absent from the peripheral blood although they have been detected in lung and lymph node biopsies.

Pathogenesis and Pathology

A clear explanation for the low percentage of those with lymphatic filariasis who develop TPE is lacking. Patients with TPE demonstrate marked humoral immune hyperresponsiveness, with elevated levels of total IgE and antifilarial IgM and IgE in both blood and lung epithelial lining fluid that decrease in response to antifilarial treatment.[79,80] A specific IgE-inducing filarial antigen also demonstrates homology with human gamma-glutaryl transpeptidase present in lung epithelium, suggesting molecular mimicry may induce an autoimmune response.[78] Exuberant eosinophil trafficking to the lungs driven by IL-4, IL-5 and eotaxin in response to microfilariae may also play a pathogenic role. Eosinophil degranulation products such as eosinophil-derived neurotoxin and major basic protein are hypothesized to contribute to TPE pathology although genetic polymorphism studies of these genes to date are inconclusive.[81,82]

The histopathologic lesions of early TPE demonstrate histiocytes in the pulmonary interstitium and alveoli.[78] However, as infection progresses, eosinophilic infiltrates develop throughout the lung tissue and can form abscesses or eosinophilic granuloma in severe cases.[79] Finally, chronic untreated disease can progress to fibrosing alveolitis and honeycombing.

Clinical Manifestations

The hallmark clinical syndrome of TPE is an insidious, nonproductive, paroxysmal cough that is worse at night. It can also be associated with fatigue, low grade fevers, shortness of breath, and wheezing, frequently leading to misdiagnosis as asthma especially in nonendemic areas.[83,84] Pulmonary function testing usually reveals a restrictive pattern with moderate concomitant airway obstruction and often reductions in diffusion capacity.[79] Chest radiographs may be normal or demonstrate reticulonodular opacities or miliary patterns in the mid to lower lung zones. End-stage disease can progress to pulmonary fibrosis and cor pulmonale. Prototypical laboratory testing demonstrates marked elevation in peripheral blood and bronchoalveolar lavage (BAL) fluid eosinophilia, elevated serum IgE levels (>1000 units/mL), and elevations in anti-filarial antibody levels.[78,83]

Diagnosis

The differential diagnosis for TPE includes other helminthic pulmonary syndromes (particularly strongyloidiasis or Löeffler's syndrome related to *Ascaris* or hookworms) and infectious and noninfectious eosinophilic pneumonias. Strongyloidiasis is important to exclude since corticosteroids can lead to dissemination with this infection. Since patients with TPE generally lack microfilariae or filarial antigens in their blood, a gold-standard diagnostic test is lacking to distinguish it from other mimics. However, diagnostic criteria have been proposed, including: (1) appropriate exposure history (mosquito bite) in an endemic region; (2) compatible clinical syndrome and radiographic findings; (3) elevated serum IgE levels and peripheral blood eosinophilia (>3000 cells/mm^3); and (4) elevated serum IgG and IgE antifilarial antibodies.[78] A clinical response to the recommended treatment of diethylcarbamazine (DEC) also supports the diagnosis.

Treatment

The recommended treatment for TPE by the WHO is DEC given orally 6 mg/kg divided in three daily doses for 21 days.[78] DEC rapidly kills both the microfilariae and adult worms, with rapid improvement in symptoms and lung function within 1 month of treatment initiation if given within the first few years of the disease. However, a persistent low-grade eosinophilic alveolitis can persist following treatment. Corticosteroids have been used as adjunctive therapy, but clinical trials have not been conducted to define the optimal dose and duration. Approximately 20% of cases will recur within 5 years necessitating a second course of DEC therapy.[79] Treatment is not successful at reversing pulmonary fibrosis or impaired lung function in later stage disease. DEC is not available currently in the US but can be obtained via eIND. Other treatments such as ivermectin, albendazole, or doxycycline to treat the symbiotic *Wolbachia* associated with filariasis are part of the WHO mass drug administration campaigns to eradicate global filarial disease, but these agents do not have an established role in TPE.[78,85]

■ Dirofilariasis

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of dirofilariasis.

Etiology

Dirofilariasis is caused by infection from the filarial nematodes in the genus *Dirofilaria* and is the most common zoonotic filariasis. Unlike other human filarial infections restricted to tropical and subtropical regions, it has a worldwide distribution.[86] While subcutaneous dirofilariasis is caused by other species, human pulmonary dirofilariasis (HPD) is primarily caused by infections with the dog heartworm, *Dirofilaria immitis*. Dirofilariasis is transmitted to humans by the bites of mosquito intermediate vectors, and the most important animal reservoir are dogs. Although the true incidence of disease is unknown, reported cases track with areas of canine hyperendemicity such as the southeastern US.[87]

Pathogenesis and Pathology

Developing adult worms reside in the canine right ventricle and pulmonary arteries and produce microfilariae, which are then taken up by mosquitoes in a blood meal. In the human accidental host, the developing worms pass through the right ventricle before lodging in small pulmonary arterial beds where they cause a local vasculitis and inflammatory response before dying.[87] Histopathology demonstrates a dead worm with a small pulmonary infarct and vasculitis within a background of granulomatous or eosinophilic inflammation (Fig. 136-3).[87] Mature adult worms and microfilariae are not typically detected in humans.

Clinical Manifestations

The classic presentation of HPD is an asymptomatic pulmonary nodule or coin lesion on routine chest imaging.[88] The lesions are typically solitary, round, 1–4 cm in size, with sharp borders located on the periphery of the lung, and often are mistaken for malignancy. When symptomatic, patients with HPD present with cough, chest pain, or hemoptysis. Eosinophilia is seen in less than 15% of cases.

Diagnosis and Treatment

Definitive diagnosis involves identification of the worm in a biopsy or autopsy specimen. Serology and tissue PCR are available but rarely needed. The only treatment is surgical removal of the worm, which is typically achieved during the diagnostic workup.

Toxocariasis

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of toxocariasis.

Etiology

Toxocariasis occurs worldwide and is primarily caused by infection with *Toxocara canis*, and less frequently by *T. cati*.[89] In the US, the seroprevalence of toxocara is estimated at about 5%.[90] Infection is more common in those living in poverty.[90,91]

The life cycle of *T. canis* and *T. cati* occurs in the dog and cat, respectively. Eggs are shed in the stool of dogs and cats and become infective three weeks later. Humans are accidental hosts. The predominant route of infection is ingestion of infective eggs found in contaminated soil and fruits or vegetables.[92] A less common route of infection is ingestion of undercooked meat containing larvae from intermediate hosts like swine, cattle, rabbits, or chickens. Once the eggs reach the intestine, they release larvae, which penetrate the intestinal mucosa, gain access to the venous circulation and can be transported to virtually any organ.

Clinical Manifestations

Most infected individuals are asymptomatic. The damage caused by migrating larvae, eosinophilic infiltrates, and eosinophilic granulomas are responsible for the clinical manifestations. Two clinical entities encompass the clinical manifestations of toxocariasis: visceral larva migrans (VLM) and ocular larva migrans (OLM). These syndromes may occur simultaneously, sequentially, or independently. VLM predominantly affects children less than 5 years of age, and the lungs, liver, spleen, and central nervous system are the organs most commonly affected. It is characterized by fever, anorexia, chronic nonproductive cough, dyspnea, wheezing, hepatomegaly, splenomegaly, seizures, eosinophilia, and hypergammaglobulinemia. The most common chest radiograph findings are bilateral peribronchial and parenchymal infiltrates.[93] The described CT findings are multifocal pulmonary nodules with surrounding ground glass opacities.[13] OLM largely affects children 5 to 10 years of age. The most common presentation is unilateral decrease in visual acuity and strabismus; uveitis, scleritis, and endophthalmitis have also been described.[94–96]

Diagnosis

Enzyme linked immunosorbent assays (ELISA), using recombinant antigens, have the best diagnostic performance for toxocariasis. These assays cannot differentiate between infection with *T. canis* and *T. cati*. The sensitivity and specificity are about 78% and 92%, respectively.[89] Although the definitive diagnosis is made by detecting larvae in the affected tissue, this is rarely performed. The diagnosis of OLM relies on the ophthalmologic exam as the sensitivity of ELISA is lower in this setting, and the titers are often low or negative.[97,98]

Treatment

Most patients with mild symptoms due to VLM have a self-limited course and do not require antihelminthic therapy.[99] For patients with moderate to severe symptoms of VLM, albendazole (400 mg orally twice a day for 5 days) is recommended.[100] Some experts advocate for corticosteroids in those with severe manifestations to mitigate the immune response to dying larvae during therapy. For OLM, treatment with albendazole (400 mg oral twice day for 14 days) and corticosteroids are recommended. Patients with severe manifestations may require surgical intervention.[94,101,102]

Echinococcosis

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of echinococcosis.

Etiology

Echinococcosis is caused by human infections from the larvae of zoonotic cestodes in the genera *Echinococcus*. While four species cause human disease (*Echinococcus granulosus*, *E. multilocularis*, *E. vogeli*, and *E. oligarthus*), the most common etiology in pulmonary disease is the dog tapeworm *E. granulosus*, the causative agent of cystic echinococcosis (CE) or hydatid disease. It has recently been recognized that *E. granulosus* represents a complex of 10 distinct genotypes, some of which have been elevated to new distinct species.[103] With a worldwide distribution, it is endemic in the pastoral communities of South America, Australia, eastern Europe, north Africa, the Middle East, central Asia, and western China although there are reports of autochthonous disease in North America.[103,104]

The infection life cycle is maintained through ingestion by the definitive host (usually domestic dogs, foxes, wolves, or other canids) of the hydatid cyst form in the infected viscera of the intermediate host (e.g., sheep, pigs, cattle, goats). The cyst matures into the adult tapeworm in the canine intestine and then sheds its embryonated eggs in the feces. Humans become accidentally infected either from ingestion of eggs in contaminated food and water or close contact and handling of dogs.[105] In humans, the embryo oncospheres are released in the stomach, penetrate the intestines, and then spread through the bloodstream to the liver or other organs where they mature into the metacestode cysts (Fig. 136-4). The lungs are the second most common location (20%) in CE after the liver (80%).[104,106] Usually unilocular in the case of CE but multilocular in other species, the maturing cyst forms a space-occupying lesion with an inner germinal layer that produces protoscolices and daughter cysts, which can seed other tissues upon cyst rupture.

Pathogenesis and Pathology

While liver involvement is predominant in adults, lung disease is more frequently detected in children whose lungs accommodate faster cyst growth.[104] The cysts have three layers: an outer host-derived pericyst, which constitutes compressed lung and a granulomatous inflammatory response which progresses to fibrosis; a middle or laminated layer; and the inner endocyst or germinal layer (Fig. 136-5), which deposits both sediment (hydatid sand) and daughter cysts into the enlarging cyst. The cyst gradually grows over the course of years to decades until it causes symptoms due to mass effect. Eventually, the cyst may degenerate into a calcified mass lesion. On the other hand, a viable cyst may acutely rupture

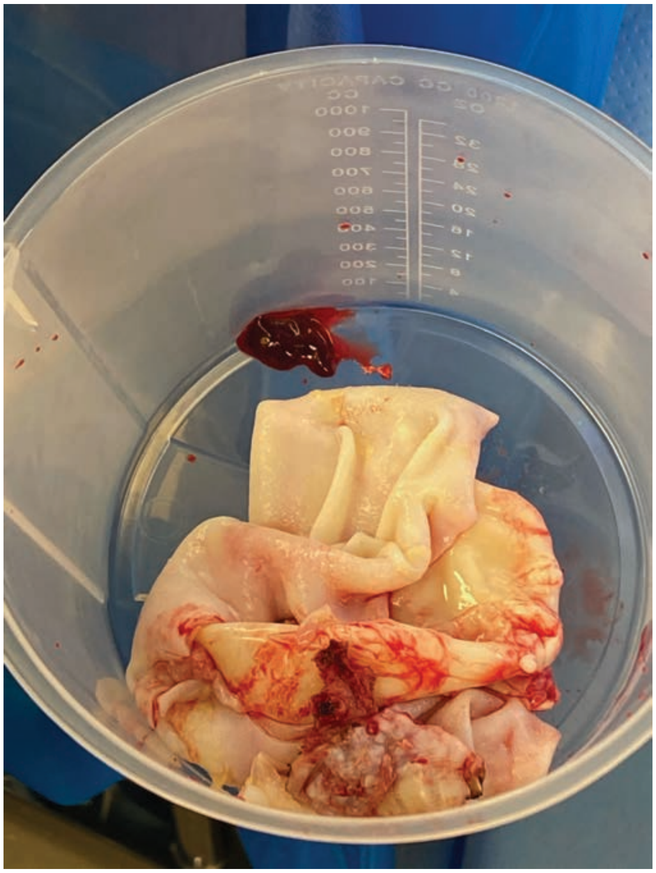

Figure 136-4 Pulmonary hydatic cyst. *(Reproduced with permission from Dr. John Waters.)*

either into the bronchial tree causing expectoration of cyst material in sputum or into the pleural space leading to pneumothorax, effusion, or secondary seeding of new daughter cysts. The cyst fluid is also highly immunogenic so rupture, either spontaneous or iatrogenic, can lead to acute hypersensitivity or anaphylactic reactions. Cysts may also become secondarily infected leading to lung abscess. Lung involvement with other species besides *E. granulosus* is much rarer but can occur with infiltration or spread from the primary hepatic site.[106]

Clinical Manifestations

Pulmonary hydatid cysts often are asymptomatic and found incidentally on imaging. Children are more likely to be asymptomatic even with very large cysts, likely due to greater lung elasticity and weaker immune responses.[104] Commonly described symptoms include cough, chest pain, dyspnea, or less often hemoptysis. An abrupt change in symptoms usually heralds a cyst complication, either cyst rupture or secondary bacterial infection. Pulmonary cysts tend to be unilateral (50–80%), solitary (60%) and have a predilection for the lower lobes, with up to 35% of individuals having concomitant hepatic involvement.[107,108] Laboratory studies are generally non-specific with peripheral eosinophilia seen in less than 25% of cases.

Diagnosis

The primary diagnostic modality for pulmonary CE is compatible imaging in the appropriate epidemiologic and clinical context. On chest radiographs, cysts usually manifest as well defined, round masses of uniform density that range in size from 1 to 20 cm in diameter.[107] Less commonly, an air-fluid level in the cyst due to detachment of the endocyst can lead to a "water lily" or "meniscus" sign. Chest CT scan may be useful in complicated cysts to define secondary infection with contrast enhancement around the cyst wall, communication with the bronchial tree, or additional smaller cysts (Fig. 136-6).[104] Although commonly used in staging of hepatic disease, ultrasound is rarely used except for pleural disease or cysts adjacent to the thoracic wall.

Serologic testing by either ELISA, indirect hemagglutination, or latex agglutination can serve as adjunctive confirmation but generally has lower sensitivity in lung compared to hepatic disease (50–60% vs. 85–98%).[106] Positive tests should be confirmed using Western blot for purified antigens since specificity is limited by cross-reactivity with other helminth diseases, malignancies, and autoimmune disease. Cyst complications or multiorgan involvement are associated with higher seropositivity rates.[108] Direct microscopy of the protoscolices or other parasite features from aspirated cyst

fluid or surgical histopathology is also diagnostic. WHO expert consensus guidelines, last updated in 2009, summarize key diagnostic and management recommendations.[106]

Treatment

The mainstay of treatment for pulmonary hydatid disease is surgery, which can both confirm the diagnosis and treat local complications.[106] The primary goal of surgery is to remove as much of the cyst as possible while avoiding intraoperative spillage and dissemination. Current surgical approaches favor complete cyst excision either via enucleation, cystotomy (Fig. 136-7), or removal after aspiration while preserving as much of the lung parenchyma as possible, with low rates of recurrence seen at less than 2%.[109] More extensive resection is reserved for giant cysts or when complicated by secondary bacterial abscesses. Use of hypertonic saline-soaked surgical drapes to protect the operative field and cavity marsupialization or surgical drain placement after removal are often required.[104,110]

Chemotherapy with benzimidazoles is reserved for small cysts or when surgery is not feasible. While mebendazole was previously used, albendazole is currently the preferred agent due to improved bioavailability. A prolonged course of albendazole 400 mg twice daily for three to six months may be effective in small, uncomplicated cysts.[104] Key side effects include hepatotoxicity, leukopenia, hair loss, and GI distress. The use of albendazole in the perioperative and post-operative periods and its combination with praziquantel for synergy have shown promise of improved efficacy in hepatic disease, but data are limited in pulmonary disease.[111] The "PAIR procedure" (*P*ercutaneous *A*spiration, *I*njection of cysticidal agent, and *R*e-aspiration) often done for hepatic cysts is not recommended for pulmonary cysts due to higher complication rates.[106]

■ Schistosomiasis

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of schistosomiasis.

Etiology

Schistosomiasis is caused by the blood flukes (trematodes) from the genus *Schistosoma*, and represents one of the most common neglected tropical diseases, with more than 200 million infections worldwide. Endemic foci of disease exist in Africa, southeast Asia, the Middle East, and South America, with the majority of cases in Sub-Saharan Africa. Five major species, each with specific geographic distribution and tissue tropism, cause clinically significant human disease: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*.[112]

Human infection begins with the free-living cercariae, which are shed by freshwater snails, directly penetrating intact skin. The cercariae lose their tail to transform into schistosomula and remain in the subcutaneous tissue for about 48 hours before sequentially migrating through the blood to the heart, lungs and then liver. Here, they mature into the adult male or female worms before reaching their ultimate destination in the genitourinary (*S. haematobium*) or mesenteric (all other species) veins. Adult worms shed eggs through the urine or feces into the environment, where they hatch into miracidia that infect aquatic snails to complete the life cycle. However, the eggs may deposit in other human tissues leading to clinical disease.

Pathogenesis and Pathology

Schistosomiasis pathogenesis is typically divided into acute and chronic phases although the timing and distinctions of these phases are being reconsidered.[112,113] Acute schistosomiasis syndrome (often referred to as "Katayama fever") usually occurs 2 to 8 weeks after exposure and is related to a systemic hypersensitivity reaction to migrating schistosomula and/or circulating antigens and immune complexes prior to the onset of egg production and deposition (oviposition). Pathologic specimens from this phase are rarely collected but demonstrate eosinophilic infiltrates and abscesses in the airspaces and pulmonary capillaries without evidence of the eggs.[112]

In contrast, chronic schistosomiasis occurs following years of chronic or repeated infection and is directly related to the duration and burden of eggs trapped in the end organ tissue. Since *S. haematobium* adult worms reside in the urinary vesical veins, eggs can directly enter the inferior vena cava and embolize to the pulmonary vessels at any stage of infection. The other species, principally *S. mansoni*, produce hepatosplenic schistosomiasis, which leads to non-cirrhotic portal hypertension; pulmonary embolization is a later finding after portocaval shunting develops. Once the ova reach the pulmonary circulation, the pathologic hallmark are granuloma formations (Fig. 136-8) in the arterioles and airspaces, progressing to an obliterative arteritis and eventually fibrosis causing pulmonary arterial hypertension (PAH).[112] However, the inciting embolization can also trigger autonomous, ongoing inflammation, principally mediated by tissue growth factor-beta, leading to plexiform or angiomatoid vascular lesions reminiscent of those seen in idiopathic PAH (iPAH).[114]

Finally, a presentation of pulmonary nodules due to clusters of deposited eggs surrounded by granuloma formation in the lungs has recently been described, which occurs both in the acute and early chronic phases.[115,116] These lesions resolve with treatment and are not associated with fibrosis or PAH, suggesting an intermediate stage. It has also led to the hypothesis that adult worms may migrate through the lungs and other ectopic organs and shed eggs *in situ* more commonly than previously recognized.

Clinical Manifestations

Acute schistosomiasis syndrome manifests as acute onset fevers, fatigue, myalgias, non-productive cough, and bronchospasm and

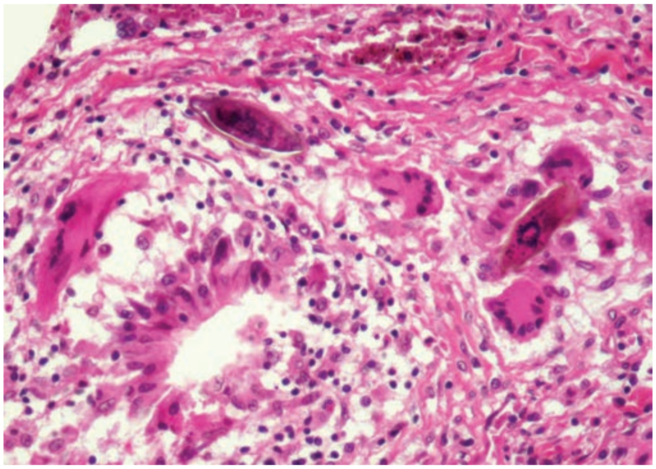

Figure 136-8 Lung biopsy demonstrating *Schistosoma japonicum* ova with surrounding granulomatous reaction on hematoxylin eosin stain at 20× magnification. *(Reproduced with permission from Dr. Dominick Cavuoti.)*

occurs almost exclusively in travelers or tourists coming from non-endemic regions.[112] Additionally, the pulmonary symptoms may become predominant several weeks after the febrile illness. With a compatible clinical syndrome and epidemiologic exposure, marked peripheral eosinophilia, elevated IgE levels, and patchy interstitial infiltrates or scattered micronodules with or without ground-glass, best seen on CT scan, are suggestive.[107] Radiographic findings may show up only after anti-helminthic treatment.

Often accompanied by the classic genitourinary or GI *Schistosoma* sequelae, the spectrum of chronic pulmonary schistosomiasis ranges from asymptomatic imaging abnormalities, chronic cough, chest pain or hemoptysis to end-stage PAH and cor pulmonale. A review of 10 cases of chronic pulmonary schistosomiasis described radiographic findings on high-resolution CT including lung consolidations, solid pulmonary nodules with peri-nodular halos, ground glass opacities, and hilar lymphadenopathy, all of which resolved with treatment.[117] Finally, chronic untreated or recurrent infection can lead to PAH and cor pulmonale which is indistinguishable clinically from other causes. Although limited by varying diagnostic criteria and lack of systematic screening in endemic areas, the current estimated prevalence of PAH in those with chronic hepatosplenic schistosomiasis is 5–10%.[114] The clinical presentation of those with schistosomiasis-related PAH appear similar to those with iPAH, but their hemodynamic profiles, response to vasodilator therapy and short-term survival appear more favorable based on a recent systematic review.[118]

Diagnosis

Diagnosis of active schistosomiasis involves microscopic identification in the urine or stool of the *Schistosoma* eggs, which can differentiate the various species.[119] However, sensitivity is poor even with serial testing in both acute and low burden infections. Serologies including ELISA and immunoelectrotransfer blot are primarily useful in returning travelers and non-endemic areas, and rapid antigen and molecular PCR-based diagnostics are becoming more widely available.[119] Demonstration of the ova in bronchoscopic samples or tissue biopsies are also confirmatory.

Treatment

The preferred treatment for active schistosomiasis is praziquantel, which targets the adult worms and prevents further oviposition.[120] The recommended dosages are either 40 mg/kg for one day (in one or two divided doses) for *S. haematobium*, *S. mansoni*, or *S. intercalatum* or 60 mg/kg for one day (in two divided doses) for *S. japonicum* or *S. mekongi*. Persistence of viable eggs on urine or stool microscopy at least 6 weeks after initial treatment would warrant retreatment with praziquantel. In acute schistosomiasis syndrome, corticosteroids are the primary treatment, with praziquantel given only after symptoms are fully resolved usually 4 to 6 weeks later. Antihelminthic therapy can reverse pulmonary nodules due to deposited eggs but not irreversible lung pathology in the later stage disease.

■ Paragonimiasis

Below we consider the etiology, pathogenesis, clinical manifestations, diagnosis, and treatment of paragonimiasis.

Etiology

Paragonimiasis is caused by lung flukes (trematodes) from the genus *Paragonimus*, with more than 15 species implicated in human disease. The disease is commonly acquired by consumption of raw, undercooked or pickled crustaceans (freshwater crabs and crayfish) infected with the metacercariae although infection from wild game meat such as boar and deer are reported.[121] It causes more than 20 million infections globally with the highest prevalence in southeast Asia where the predominant species is *Paragonimus westermani*; other species cause disease in Africa and South and Central America.[122] Autochthonous cases caused by *P. kellicotti* have been reported in North America associated with infected freshwater crayfish.[123]

Following human ingestion from infected food sources, the metacercariae excyst, penetrate the intestinal wall, and migrate from the abdominal cavity through the diaphragm into the pleural space and lungs. In the lungs, they mature into reddish-brown, hermaphroditic adult worms in cystic cavities, which produce golden-brown operculated eggs (~100 × 55 um in size) (Fig. 136-9) that are coughed up in sputum or swallowed and shed in the feces. Once in the environment, the eggs hatch and go on to complete the non-human life cycle in its two intermediate hosts, freshwater snails and crustaceans.

Pathogenesis and Pathology

The pathology of *Paragonimus* infection correlates with the three disease stages: (1) primary infection and migration; (2) encystation; and (3) death. Migration of the lung flukes through the pleural cavity and lungs induces inflammation, hemorrhage, and tissue necrosis as they "tunnel" from the periphery toward the bronchioles.

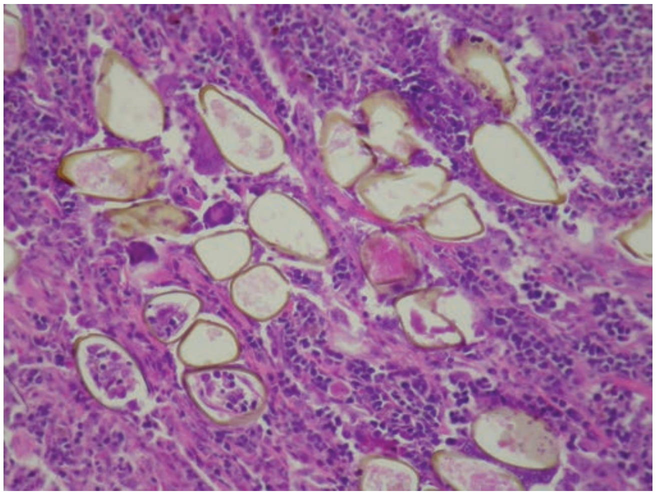

Figure 136-9 Lung biopsy demonstrating *Paragonimus westermani* operculated eggs on hematoxylin eosin stain at 100× magnification. *(Reproduced with permission from Dr. Dominick Cavuoti.)*

Surrounding neutrophilic and eosinophilic inflammation, with Charcot-Leyden crystals, can be seen along these tracks. The worms then encyst in the lungs, forming clusters of encapsulated cysts that communicate with each other or the bronchi and form fistula which allow eggs entry into the airways. Finally, with death of the worms, the cyst collapses leading to fibrosis or calcification. Ectopic migration of the flukes out of the lungs can spread to other areas, most commonly the central nervous system, abdominal viscera, and skin.

Clinical Manifestations

The clinical presentation varies based on the duration of infection and helminthic burden. Following a nonspecific prodrome of fever, diarrhea, abdominal pain, cough and urticaria a few weeks after infection, established pulmonary infection manifests after an incubation period of 2 to 16 weeks. The classic presentation involves fevers, cough, hemoptysis, and peripheral eosinophilia.[124] More chronically, the clinical presentation resembles chronic bronchitis or bronchiectasis marked by copious, rust brown, blood-tinged sputum which contains parasite eggs, necrotic material, and Charcot-Leyden crystals. The presence of peripheral eosinophilia, seen in 45–80% of cases, can be a key discriminating feature from other more common entities such as tuberculosis or malignancy.[124,125]

In early disease, chest radiographs demonstrate non-specific opacities from the migrating worms or may be normal in up to 20% of cases. In later disease, radiographic signs may include lobar consolidations, cystic or cavitary lesions, calcified nodules, hilar enlargement and pleural effusions.[126] Chest CT may demonstrate a classic "ring sign" of a subpleural nodule with central necrosis or surrounding ground glass, often accompanied by characteristic linear opacities to the pleural surface due to worm migration tracks.[126,127] Pleural fluid studies demonstrate an exudate with elevated eosinophilia, total protein and lactate dehydrogenase accompanied by low glucose and pH. Recognized in up to 25% of hospitalized patients with paragonimiasis, the most common extrapulmonary manifestation is neurologic disease, which can present as eosinophilic meningitis or ring-enhancing mass lesions presenting with headaches, vision changes and seizures.[122]

Diagnosis

Diagnostic microscopy can demonstrate the characteristic *Paragonimus* eggs in sputum, feces, BAL, or tissue biopsy. Multiple samples are needed since the yield of a single sputum or stool specimen is less than 40%.[122] For cases with negative microscopy, commercial ELISA serologies and a CDC-developed immunoblot are helpful with demonstrated high sensitivity (>90%) for *P. westermani*[128]; a Western blot specifically for the *P. kellicotti* antigens may be more useful for cases acquired in North America. Molecular diagnostics including PCR and multiplex protein microarrays are in development.

Treatment

The preferred treatment for paragonimiasis is praziquantel at a dose of 25 mg/kg three times daily for 2 to 3 days.[122] Symptoms improve rapidly while clearance of eggs from sputum and radiographic resolution may take weeks to months. Recurrent pleuropulmonary disease may require a second course of therapy.[129] An alternative regimen is triclabendazole at a dose of 5 mg/kg per day for 3 days or 20 mg/kg divided in two doses for one day.[130] In patients with concomitant CNS disease, corticosteroids are given to blunt the inflammatory response to the dying worms.

CHAPTER 137

Nocardiosis and Actinomycosis

Daniel N. Maxwell
Reuben J. Arasaratnam
Alejandro Restrepo
Tara M. Babu

INTRODUCTION

Nocardia, a Gram-positive, filamentous bacteria, causes the rare infection known as nocardiosis and belongs to the *Nocardia* genus in the actinomycetes group. Ubiquitous in nature, *Nocardia* spp. are found worldwide in soil, water, and vegetation.[1] Actinomycosis is an indolent infection caused by anaerobic or microaerophilic bacteria primarily belonging to the genus *Actinomyces*. Each is discussed in detail below.

NOCARDIOSIS

The clinical spectrum of nocardiosis ranges from localized to disseminated disease in both animal and human hosts. It is an opportunistic pathogen, primarily infecting immunocompromised individuals. New molecular techniques have improved *Nocardia* spp. identification. Clinical manifestations mainly include cutaneous, pulmonary, and disseminated disease involving the brain. Treatment often requires regimens of multiple antibiotics for a prolonged duration of therapy.

■ History and Classification

In 1888, Edmon Nocard first isolated an aerobic actinomycetes, later named *Nocardia*, in cattle afflicted with bovine farcy, a lymphatic disease.[2] Two years later, Eppinger described the first human case of *Nocardia* infection in a man with both "pseudo tuberculous" pulmonary disease and central nervous system infection.[3] In 1921, Henrici and Gardner reviewed the world literature for every case of aerobic acid-fast actinomycosis and identified only 26 cases.[4] Despite the paucity of cases, they succeeded in describing aspects of nocardiosis that have influenced our current understanding; infection occurs via inhalation resulting in pulmonary disease, the occurrence of disseminated disease (i.e., the brain), and a disease course of approximately 6 months.

Molecular diagnostic techniques identifying key housekeeping genes such as 16S rRNA, gyrB, secA, hsp65, and/or rpoB have allowed a more comprehensive characterization of the taxonomy.[5] Consequently, *Nocardia* spp. have undergone significant taxonomic changes and species reclassification. The *Nocardia* genus consists of more than 80 species.[6] More than 40 species are associated with infections in humans.[6] Elucidation of further *Nocardia* species is ongoing. Commonly identified species responsible for infections in humans are *N. asteroides*, *N. nova*, *N. farcinica*, *N. otitidiscaviarum*, *N. transvalensis*, *N. brasiliensis*, *N. brevicatena*, *N. abscessus*, *N. cyriacigeorgica*, *N. veterana*, *N. paucivorans*, *N. wallacei*, *N. blacklockiae*, *N. elegans*, *N. concava*, and *N. cassostreae*.[7] Pulmonary infection is frequently caused by *N. cyriacigeorgica*, *N. nova* complex, and *N. farcinica*, while *Nocardia brasiliensis* is responsible for skin and soft tissue infections.[8]

■ Environmental Epidemiology

Nocardia spp. are not human commensals but are environmental saprophytes found widely in aquatic, vegetative, and soil-based environments.[1] Human infection occurs primarily from inhalation, direct skin/soft tissue inoculation, and rarely ingestion of bacteria. Nocardiosis occurs in men more than women. In the United States the primary route of *Nocardia* infection is secondary to inhalation. Some authors suggest a higher incidence of pulmonary nocardiosis in geographic regions such as the Southwest United States, where dry, windy and dust-laden climates potentiate aerosolization of *Nocardia*.[9] Nosocomial nocardiosis outbreaks are described in catheterized patients, postsurgical patients, and immunocompromised patient wards.[10–13] Sources of infection identified are proximal construction sites, fomites isolated from staff hands, contaminated air, and dust particles laden with bacteria.[13–15] In a nosocomial outbreak investigation of five cases of postoperative *N. farcinica* sternotomy infection, four of the patients had similar ribotype isolates as an isolate recovered from an anesthesiologist's hand.[14] *Nocardia* spp. infections are rarely implicated in intravascular catheter infections and peritoneal dialysis catheter infections in immunocompromised hosts.[10,16,17] Additionally, a cosmetic injection was responsible for an outbreak of *N. cyriacigeorgica* soft tissue infection (n = 8), confirmed by multilocus sequence typing.[18] Recently, two cutaneous nocardiosis cases occurred in immunocompetent hosts following intralesional steroid injections.[19]

■ Disease Pathogenesis

The current conceptual framework of *Nocardia* infection supports an initial immune response by macrophages and neutrophils that is able to suppress but not eliminate the bacteria.[20,21] IL-17 production by γδ T lymphocytes is important in neutrophil recruitment in nocardiosis.[22] Ultimately, clearance of the organism is dictated by T cell–mediated killing.[23] The integral role of neutrophils and T cells in the control and elimination of the disease is illustrated clinically by the higher incidence of disseminated disease in patients with neutrophil defects (e.g., chronic granulomatous disease). Impaired T-cell immunity is a known risk factor for *Nocardia* infection (discussed below). Humoral immunity is not believed to play a significant role in protection from *Nocardia* infections.

Nocardia is an opportunistic pathogen that primarily infects immunocompromised individuals. However, it does have the ability to infect immunocompetent hosts, including up to one-third of all cases in a retrospective study conducted from 1972 to 1974.[24] *Nocardia* virulence factors enable evasion of the host immune system. *Nocardia* is a facultative intracellular organism that inhibits phagosome–lysosome fusion,[25] resists phagosome acidification,[26] causes cell wall lipid induction of macrophages to produce proinflammatory cytokines (IL-1B, IL-6, and CCL-2), and suppresses microbicidal effects of macrophages and dendritic cells.[27] *Nocardia* bacteria undergoing log growth phase replication have the ability to evade phagocytosis.[28] Additionally, a critical virulence factor of *Nocardia* spp. is the production of superoxide dismutase and catalases enabling resistance to oxidative killing.[29]

As previously mentioned, *Nocardia* central line–associated bloodstream infections (CLABSI) are rare. In an in vitro biofilm model, *Nocardia* spp. form dense branching networks within a heavy biofilm matrix on the surface of central venous catheters (CVC).[10] The biofilm protects the bacteria from relatively low serum concentrations of antimicrobial drugs. Exposure to high concentrations of antimicrobials, lock therapy, and removal of CVCs may be effective methods for managing biofilm production in isolated CVC infections.[10]

■ Risk Factors for Disease

In the 1970s, a national survey among infectious disease practitioners in the United States estimated the incidence of *Nocardia* infection to be between 500 and 1000 cases per year.[24] The vast majority (>80%) of infections were classified as severe pulmonary or systemic infections, and 15% of cases had no identified underlying immunosuppressive condition.[24] Due to an increasing population of patients on immunomodulating medications, the incidence of nocardiosis is increasing. A study conducted in Quebec, Canada, confirmed a significant increase from 1997 to 2008 in the annual incidence of *Nocardia* spp. from 0.33 to 0.87 per 100,000 inhabitants.[30] The majority of nocardiosis cases occur in immunocompromised patients, most commonly in the setting of solid organ and hematologic stem cell transplantation, malignancy, immunosuppressive medications, and human immunodeficiency virus.

Solid-organ Transplantation

The incidence of *Nocardia* infections in solid-organ transplant recipients is estimated to be between 0.04% and 3.5%, with infection commonly occurring within the first 2 years post-transplantation.[31–33] In a case-control study of 35 SOT patients with nocardiosis, higher incidence of nocardiosis was found in heart (2.5%) and lung (3.5%) transplant recipients compared with liver (0.1%) and kidney (0.2%) transplant recipients.[32] Heart and lung transplantation require higher net states of immunosuppression to maintain the allograft. Impaired respiratory immune surveillance and increased pulmonary diagnostic surveillance (i.e., frequent bronchoscopies) also may contribute to the high incidence of nocardiosis in lung transplant recipients.

In a large, multicenter, retrospective study in Europe, the main risk factors identified for nocardiosis in a solid-organ transplant population included older age, elevated calcineurin trough level inhibitor in the month preceding diagnosis, use of tacrolimus or corticosteroids at the time of diagnosis, and longer duration of intensive care unit stay following transplantation.[33] History of preceding cytomegalovirus disease was identified as a risk factor for nocardiosis, although it is unclear if this finding represents the immunomodulatory potential of the virus or reflects a high net state of immunosuppression in the host.[32]

The 1-year mortality rate from nocardiosis in SOT recipients ranges from 11% to 17%.[32–34] One case-control study found a 10-fold higher all-cause mortality rate in SOT recipients with nocardiosis compared to those without.[35] In a case-control study of SOT recipients with nocardiosis (n = 117), independent risk factors associated with mortality were a history of malignancy, prior invasive fungal infection, and increased transplant donor age.[33] Acute rejection and consequent increased immunosuppression in the preceding year of nocardiosis diagnosis was associated with a decreased risk of mortality.[33] The authors attributed these paradoxical findings to increased surveillance and screening for infection or potential blunting of the inflammatory response secondary to *Nocardia* infection.

Hematopoietic Stem Cell Transplantation and Malignancy

Nocardiosis occurs more in allogeneic stem cell transplant (SCT) recipients than autologous stem cell recipients.[36,37] In allogeneic SCT recipients, the risk of *Nocardia* infection within the first 2 years post-transplant is estimated from 0.3% to 1.7%.[36–38] In small case series, late infections (>500 days post-transplant) are associated with the use of high-dose corticosteroids for graft-versus-host disease.[39] In single-center cohort studies, mortality rates are as high as 40% to 50%.[39,40] Several authors have noted a correlation between delayed lymphocyte recovery, particularly CD4 T lymphocytes, and nocardiosis in the allogeneic stem cell transplant population.[41,42]

Patients with solid tumor malignancies are also at risk for nocardiosis due to immunosuppressive chemotherapy regimens. In a retrospective review of admissions at a major cancer center in the United States, spanning 1988 to 2001, 43 episodes of nocardiosis were detected (constituting an incidence of 60 cases per 100,000 admissions).[43] Sixty-four percent had an underlying hematologic malignancy and 36% had an underlying solid tumor malignancy.[43] Pulmonary infection was the most common manifestation (70% of cases), with preceding chemotherapy or receipt of corticosteroids being documented risk factors.

HIV Infection

Nocardiosis is relatively rare in individuals infected with HIV. In a retrospective analysis from 1981 to 2000, in an 1100-bed teaching hospital in Madrid, Spain, only 8 cases of *Nocardia* infection were diagnosed in those with HIV, constituting an incidence of 0.38% among the HIV population.[44] The majority of patients were male, with an average age of 28 and median CD4 counts of 35 cells/μL.[44] Of the 8 patients in this series, 2 died from progressive pulmonary infection. In several case reports and case series of *Nocardia* infection in individuals living with HIV, identified risk factors were CD4 count less than 200 or advanced AIDS, preceding use of systemic corticosteroids,[45,46] and a delay in diagnosis leading to detection at a late stage of disease.[47]

Immunosuppressive Medications

In several large cohort studies, the chronic administration of systemic corticosteroids alone, or in combination with other immunosuppressive medications, remains the most consistent risk factor for development of nocardiosis.[32,43] It is imperative to consider *Nocardia* in the differential diagnosis of a patient presenting with pulmonary infection on chronic steroids, regardless of whether there is underlying lung disease.[48,49] While the risk of *Nocardia* infection is related to cumulative use (dose and duration) of corticosteroids, cases of *Nocardia* infection occur with daily doses of prednisone as low as 10 to 15 mg daily.[50,51] The association of nocardiosis and use of other immunosuppressive agents such as TNF-α inhibition,[52] IL-6 inhibition,[53] and anti-CD20 monoclonal antibody therapy[54,55] are described in patients with autoimmune inflammatory disease. However, due to the low incidence of *Nocardia* in these populations, the limited case reports published, and coadministration of other immunosuppressants (i.e., corticosteroids), no conclusions regarding causality for nocardiosis can be drawn for these agents.

Chronic Lung Disease

The presence of chronic lung disease is considered a risk factor for the development of nocardiosis. In a large retrospective analysis carried out at a tertiary medical center between 1996 and 2013, noncystic fibrosis bronchiectasis was common in both immunocompetent (38%) and immunocompromised (10%) patients.[56] The association of chronic lung disease with nocardiosis may be related mechanistically to abnormal bronchial architecture, anatomy, and mucociliary clearance that enables establishment and interference with clearance of the organism. In addition, concomitant use of systemic steroids for several chronic lung diseases (e.g., COPD, interstitial lung disease) is likely a major contributive risk factor.

Inherited Immunodeficiencies and Genetic Syndromes

Patients with chronic granulomatous disease (CGD) possess genetic mutations in the phagocytic NADPH oxidase system leading to impaired phagocytosis and increased risk for infections, including *Nocardia*.[57] In patients with CGD, prophylaxis with IFN-γ and a sulfonamide is recommended to prevent disseminated nocardiosis.[58]

Anticytokine antibodies are an emerging cause of immunodeficiency in adults.[59] In a case-control study of otherwise immunocompetent patients with CNS nocardiosis, anti–granulocyte-macrophage colony-stimulating factor (anti–GM-CSF) autoantibodies were detected in 5 of 7 patients with nocardiosis.[59] Anti–GM-CSF antibodies have also been associated with pulmonary alveolar proteinosis and other opportunistic infections.[60,61] Lastly, idiopathic CD4 T-lymphocytopenia is a rare condition that is defined as

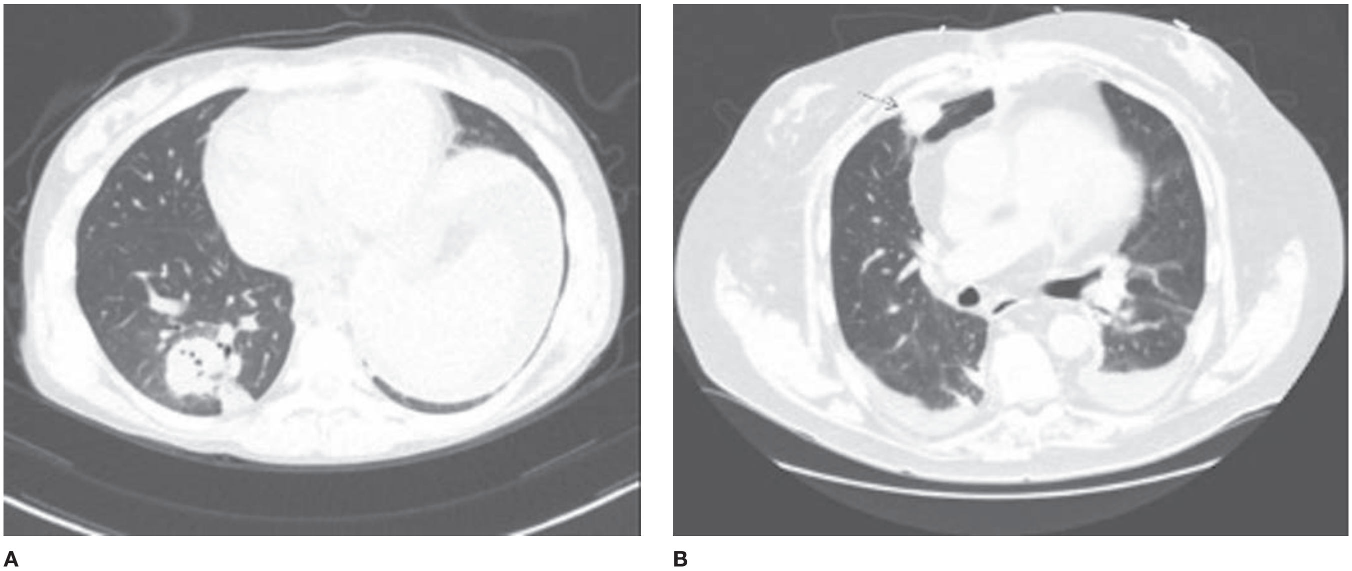

Figure 137-1 Pulmonary nocardiosis in a 17-year-old female with past medical history of a pediatric liver transplant developed a nonproductive cough. Her sputum culture was positive for *Nocardia* spp. Her brain MRI was negative for CNS infection. **A.** Axial CT image of the chest depicts a right lower lobe mass with internal foci of air. **B.** Axial CT image of the chest demonstrates a right upper lobe peripheral nodule[169] abutting the anterior chest wall pleura. *(Reproduced with permission from Sally Chuang, MD.)*

persistent CD4 T-cell lymphopenia without HIV or an alternative immunodeficiency diagnosis, which predisposes patients to opportunistic infections, such as *Nocardia* infection.[62]

■ Clinical Manifestations

Below we discuss the pulmonary and extrapulmonary manifestations of nocardiosis.

Pulmonary Nocardiosis: Clinical and Radiographic Findings

Pulmonary infection is the major clinical manifestation of nocardiosis, due to inhalation or aspiration of bacterial mycelia. Pulmonary infections represent around 50% to 70% of all nocardiosis cases.[7,45,63] The onset of nocardiosis is primarily subacute, but it may occur more acutely in immunocompromised hosts. Cough and fever are the most common symptoms described in pulmonary nocardiosis. Additionally, systemic symptoms are common, consisting of fever, chills, malaise, night sweats, fatigue, and unexpected weight loss. Chest pain, pleuritic pain, hemoptysis, and dyspnea are rare.

The spectrum of radiographic findings for pulmonary nocardiosis includes lung infiltrates, nodules, cavitation, and masses (Figs. 137-1 and 137-2). Infection can be isolated to a single lobe or present as multilobar pneumonia. The masslike appearance may be indistinguishable radiographically from malignancy. The differential diagnosis for pulmonary nocardiosis is broad and ranges

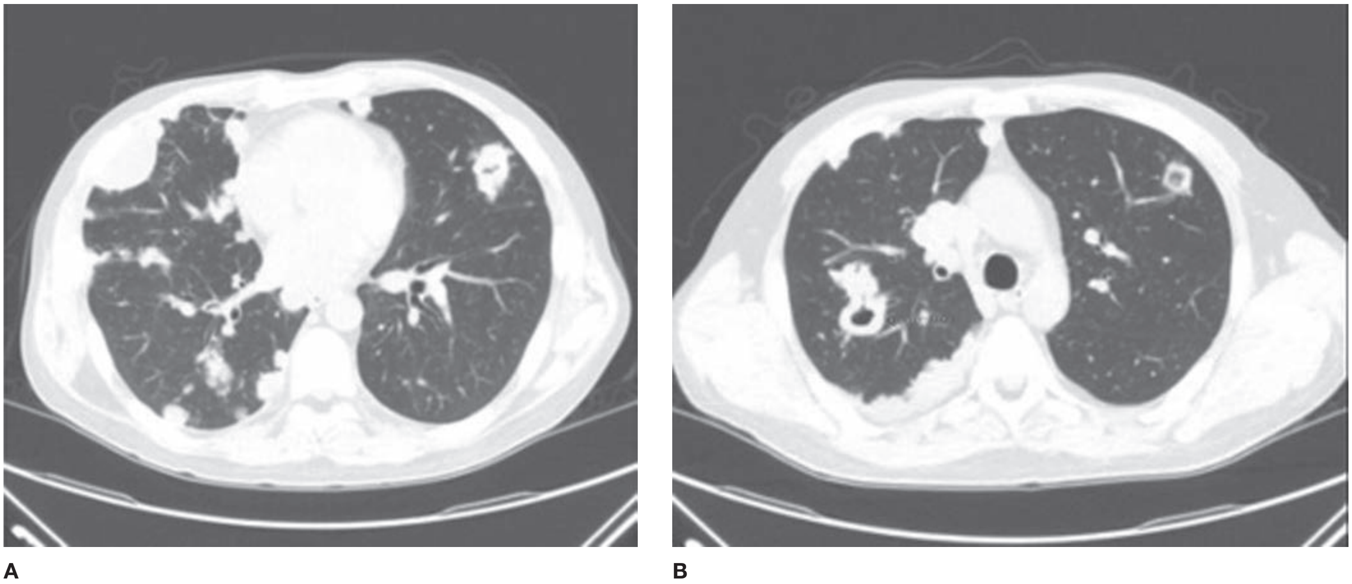

Figure 137-2 Pulmonary and CNS nocardiosis in a 36-year-old male with a past medical history of anaplastic B-cell lymphoma treated with chemotherapy (cyclophosphamide, doxorubicin, etoposide, vincristine, and prednisone) who presented to the hospital with productive cough and mild headache. **A.** Axial CT of the chest shows bilateral centrilobular nodules right > left, some of which contain foci of air. **B.** Axial CT of the chest demonstrates a large central cavitary lesion of the right upper lobe. *(continued)*

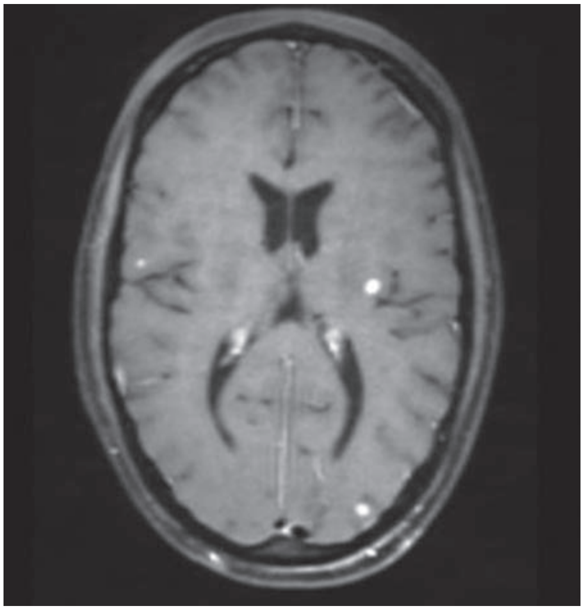

Figure 137-2 *(Continued)* **C.** MRI of the brain shows multiple, variable-sized, enhancing parenchymal lesions involving the supra- and infratentorial compartment bilaterally, the largest involving the left posterior subinsular region measuring 5 × 5 mm. *(Reproduced with permission from Sally Chuang, MD.)*

from bacterial and fungal pathogens to malignancy (Table 137-1). Pulmonary nodules are the most common radiographic presentation of pulmonary nocardiosis. In a large case-control study of 117 solid-organ transplant recipients, radiographic imaging demonstrated pulmonary nodules in 75% of cases, cavitation in 32% of cases, lung consolidation in 41% of cases, and pleural effusion in 26% of cases.[33] Fifty-six percent had multilobar involvement, and 51% had bilateral disease.[33] In a study of 25 immunocompromised and immunocompetent patients, the most common chest CT findings consisted of multiple pulmonary nodules (96%), consolidation (76%), and cavity (52%).[64] No difference was found in the CT findings between immunocompromised and immunocompetent patients.

The isolation of *Nocardia* from patients without evidence of lung infection has been shown in patients with underlying lung disease, that is, bronchiectasis or cystic fibrosis, and requires careful consideration. *Nocardia* isolation in an immunocompromised host should always be considered pathogenic, and treatment is indicated.

Extrapulmonary nocardiosis results from the hematogenous or contiguous spread of bacteria from the lung to other sites in the body. Infection may spread contiguously to the pleural space, mediastinum, pericardium, and/or vena cava. Empyema is present in one-third of cases. The central nervous system (CNS) is the most common site for extrapulmonary nocardiosis and is discussed below (Fig. 137-2). Other sites of disseminated disease are the skin and subcutaneous tissues, eyes (especially the retina), kidneys, joints, bones, and heart.[65]

Cutaneous Manifestations

Nocardia cutaneous infection often results from the direct inoculation of bacteria. Skin and soft tissue manifestations of nocardiosis are categorized into four classes: superficial soft tissue infection (cellulitis or abscess), lymphocutaneous infection, mycetoma, and manifestations secondary to disseminated disease (Figs. 137-3 and 137-4). Cutaneous lesions occur in both immunocompetent and immunocompromised hosts. Similar to *Nocardia* pneumonia, skin lesions have both acute and subacute onset, and manifest as indolent lesions, presenting days to months following inoculation.

Modified with permission from Wilson JW. Nocardiosis: updates and clinical overview. Mayo Clin Proc. 2012;87(4):403–407.

Mycetoma is a chronic, painless, progressive, and destructive bacterial or fungal infection of the skin, subcutaneous tissues, and fascia that may involve bone. Mycetoma occurs in rural, subtropical areas with a predilection for men.[66] The lesion initially presents as a nodule that can evolve a fistulous tract to the skin. Mycetoma forms following a trauma to an extremity, and pathology is consistent with suppurative granulomas, necrotizing lesions with fibrosis, and sinus formation.[66] Exudate may contain granules secondary

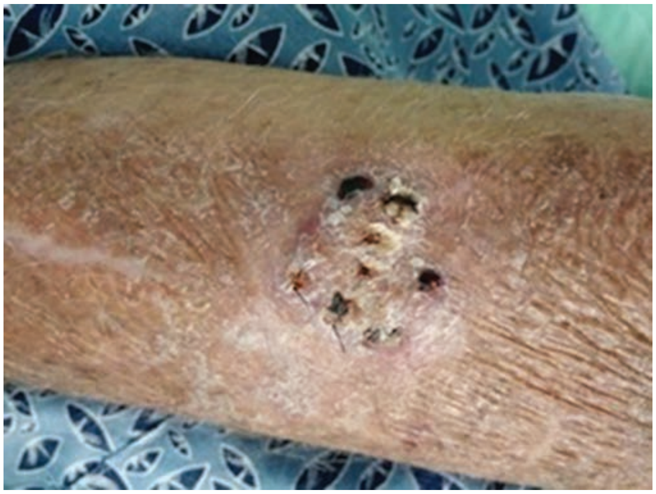

Figure 137-3 *Nocardia* skin and soft tissue infection in a 73-year-old male with a past medical history of kidney transplant who presented with skin lesions following a history of trauma related to working with wood. Skin biopsy was positive for *Nocardia otitidiscaviarum*. *(Reproduced with permission from Carolyn D. Alonso, MD, FIDSA.)*

to clumps of bacteria. In North America, South America, and Australia, *N. brasiliensis* is the *Nocardia* species primarily associated with mycetoma.[66]

In solid-organ transplant recipients, cutaneous infection represents approximately 10% of all *Nocardia* manifestations.[32,67] Cutaneous nocardiosis presents similarly to other opportunistic infections in immunocompromised hosts, and bacterial, fungal, and mycobacterial diseases should be considered. *Nocardia* cutaneous infections manifest as pustules, cellulitis, or pyoderma, often resembling typical bacterial skin and soft tissue infections due to *Streptococcus* and *Staphylococcus* species.[66] Biopsy and histopathology are diagnostic for *Nocardia* and other pathogens. Since *Nocardia* skin infection could represent sequelae of a disseminated process, we recommend imaging to evaluate for disseminated disease (i.e., pulmonary and CNS) in the immunocompromised host with a cutaneous infection.

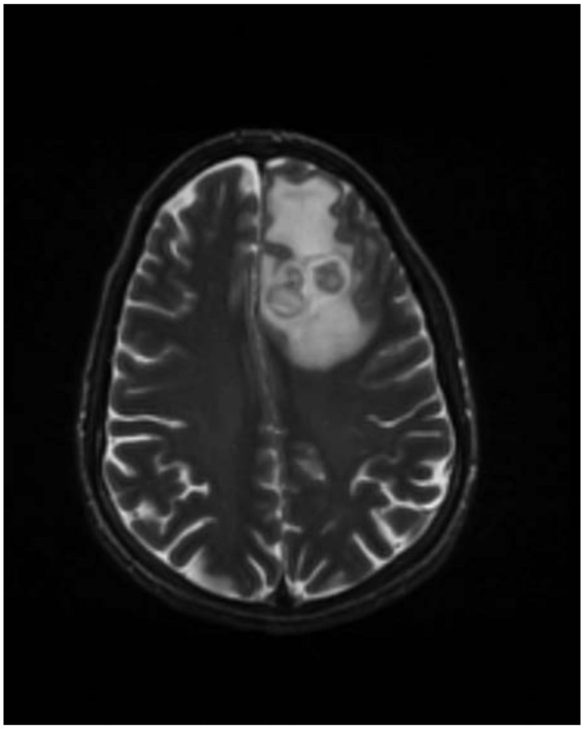

Figure 137-5 Fluid-sensitive MRI image demonstrates a left frontal brain abscess from *Nocardia asteroides* with surrounding edema in a middle-aged man with a history of amyloid treated by autologous bone marrow transplant and heart transplant. *(Reproduced with permission from Camille Kotton, MD, FIDSA.)*

Central Nervous System Manifestations

Central nervous system infection is insidious in nature and presents in one-third of nocardiosis cases and up to 44% of disseminated cases.[66] Radiographic findings, on CT or magnetic resonance imaging (MRI), consist of multiloculated, single or multiple brain abscesses within the supratentorial region (Figs. 137-2 and 137-5). Meningitis is less common. Asymptomatic brain lesions occur frequently in nocardiosis; CNS imaging (preferably MRI) should

Alonso, MD, FIDSA.)*

be considered in immunocompromised hosts and patients with pulmonary or disseminated disease. The CNS radiographic imaging of choice is MRI. Neurologic presentations in the CNS include headache, confusion, focal neurologic signs, seizures, and coma.[68] CNS infection is due primarily to hematogenous dissemination, but positive blood cultures are rarely detected.

Other Presentations of Nocardiosis

Disseminated nocardiosis is defined as the involvement of two noncontiguous organs. Disseminated disease has been associated with an all-cause mortality rate as high as 44%.[10,11] *Nocardia* bacteremia is rarely identified. Foreign materials as a prosthetic heart valve or central venous catheters are identified risk factors for *Nocardia* spp. bacteremia.[10,11]

Nocardia ocular infections are rare. Infections occur following eye trauma, ocular surgery, or ophthalmic infection secondary to hematogenous spread in the immunocompromised host.[69–71] Ocular nocardiosis manifests as uveitis, choroiditis, retinal abscess, retinal detachment, keratitis, and iritis.[8] *Nocardia* endophthalmitis can result in blindness and is associated with significant mortality.[8,69]

■ Diagnosis

The definitive diagnosis of nocardiosis is made by isolating the bacteria in culture from clinical samples. Blood cultures are positive in only 25% of patients (*Nocardia* grows in routine blood cultures, without need for fungal or mycobacterial isolators). Tissue biopsy or abscess drainage of infected sites is usually necessary. Bronchoalveolar lavage, pulmonary nodule biopsy, or skin tissue biopsies of infected sites are often performed for diagnosis. If *Nocardia* spp. is identified in pulmonary nocardiosis, it is reasonable to assume that the CNS radiographic abnormalities are due to the same process.[72] However, in the immunocompromised host there is a higher risk for concurrent pathogens and early brain tissue biopsy should be considered.

Historically, *Nocardia* is difficult to identify in the laboratory. *Nocardia* appears as a Gram-positive beaded or branching filamentous bacteria on Gram stain. The presence of *Nocardia* on Gram stain may allow for a presumptive diagnosis. Most strains of *Nocardia* possess weakly acid-fast staining properties, enabling differentiation from *Actinomyces*. In a study of 80 patients with *Nocardia*-positive cultures, 50 (64%) patients were positive by Gram stain and only 26 (51%) were also positive by modified acid-fast staining.[9]

The classic histologic finding of nocardiosis is an abscess with neutrophilic predominance and necrosis. Surrounding granulation tissue is present without extensive fibrous encapsulation. The Brown-Brenn and Gomori methenamine silver stains can be used to identify bacteria from tissue histopathologic samples[73] (Fig. 137-6).

Nocardia species identification aids in guiding therapy, as discussed below. Gene sequencing of *Nocardia* proteins (i.e., heat shock protein 65) or 16S rRNA are now the standard methodology

[a] *There are no established interpretive categories for susceptibility testing for tigecycline; a minimum inhibitory concentration ≤1 μg/mL was arbitrarily designated as susceptible.*

Data from Restrepo A, Clark NM; Infectious Diseases Community of Practice of the American Society of Transplantation. Nocardia infections in solid organ transplantation: Guidelines from the Infectious Diseases Community of Practice of the American Society of Transplantation. Clin Transplant. 2019;33(9):e13509.

for speciating *Nocardia*. Multilocus analysis may be indicated for distinguishing closely related *Nocardia* species. Additionally, matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF) is a rapid and cost-effective protein profiling methodology for identifying *Nocardia* spp. once bacterial growth is present.[74–76] However, MALDI-TOF relies on a prior validated protein profile database for the specific pathogen isolated. Uncommon bacteria species remain a challenge for MALDI-TOF MS identification.

■ Treatment

The standard treatment for nocardiosis is antibiotic therapy; adjunct surgical debridement is sometimes required. Due to the relatively low incidence and wide variability in the clinical presentation of nocardiosis, no prospective controlled clinical trials evaluating comparative treatments exist. *Nocardia* is variably resistant to different antibiotic classes. Empiric therapy consisting of two or three drugs is recommended for severe infection, particularly CNS disease, while awaiting antibiotic susceptibility testing (Table 137-2). Due to favorable susceptibility patterns, decreased *Nocardia*-associated mortality, lower infection relapse risk, and historic clinical experiences, sulfonamides are considered the drug of choice for nocardiosis (Table 137-3).

Historically, the most data and clinical experiences for nocardiosis treatment are with sulfonamides.[77,78] In the United States, trimethoprim-sulfamethoxazole (TMP-SMX) is the only parenteral sulfonamide and the preferred sulfonamide for nocardiosis. TMP-SMX has shown excellent clinical efficacy for nocardiosis treatment.[77,78] Most patients demonstrate clinical improvement from nocardiosis 7 to 10 days following initiation of empiric sulfonamide therapy.[6] Increasing sulfonamide resistance in *Nocardia* isolates highlights the need for species identification and antibiotic susceptibility data. Resistance rates range from 3% to 10% and are reported as high as 20% in certain *Nocardia* spp.[79] A cross-sectional surveillance study conducted in the United States found TMP-SMX and/or sulfamethoxazole resistance as low as 2% (n = 552).[80]

The recommended dose for TMP-SMX for isolated *Nocardia* cutaneous infection is 5 to 10 mg/kg/day (based on trimethoprim component) divided in 2 to 4 doses. Our recommended dosage of TMP-SMX for pulmonary, disseminated, and CNS nocardiosis is 10 to 15 mg/kg/day (based on trimethoprim component) divided in 2 to 4 doses. Renal dosing (for creatinine clearance of ~<30 mL/min) of sulfonamides is necessary and often indicated in transplant recipients. Clinical failures with sulfonamide therapy are rare; however, if TMP-SMX resistance is present alternative therapies should be considered, and this is why we often start with multiple agents. TMP-SMX intolerance is demonstrated in 20% to 50% of patients, and side effects include myelosuppression, renal failure, hepatitis, and in rare cases aseptic meningitis. In a retrospective study

IV, intravenous; PO, oral; TMP-SMX, trimethoprim-sulfamethoxazole; CTX ceftriaxone.

For severe disease, consider three-drug empiric therapy.

(n = 24) of patients with pulmonary nocardiosis, 11 of 21 (52%) patients who received TMP-SMX required antibiotic cessation due to adverse events.[81] Adverse events included pancytopenia 45.5%, gastrointestinal symptoms 18.2%, electrolyte imbalance 18.2%, renal failure 18.2%, drug fever 9.1%, and rash 9.1%. The median duration from the initiation of TMP-SMX treatment to adverse effects was 8.0 ± 5.4 days.[81] If a patient is allergic to sulfonamides, desensitization should be considered when possible.

Imipenem has variable activity in vitro and resistance is present in some *Nocardia* spp. (Table 137-2). Imipenem tends to have a better susceptibility profile than meropenem for *Nocardia* species.[82] However, meropenem is an alternative to imipenem, particularly if there is concern for imipenem lowering the seizure threshold.[83] Identified risk factors for seizure and imipenem use consist of renal dysfunction, epilepsy, and underlying CNS disease.[84] In a more recent meta-analysis, carbapenems posed a low overall risk of seizure, but the risk of seizure was higher with the use of carbapenems compared with noncarbapenem antibiotics.[85] Although imipenem was more epileptogenic than noncarbapenem antibiotics, imipenem was not more epileptogenic than meropenem in a head-to-head comparison.[85] Ertapenem should not be used for nocardiosis therapy, as it does not cover *Nocardia* well. In vitro amikacin has broad activity against *Nocardia* spp. (Table 137-2). Amikacin does not have adequate CNS penetration, and the side-effect profile of nephrotoxicity and hearing loss can be treatment-limiting. Amikacin levels require close monitoring. Imipenem and amikacin combination therapy is efficacious for the treatment of pulmonary and CNS nocardiosis in mouse models.[86] Additionally, the treatment of choice for *Nocardia* keratitis is topical amikacin.[87]

Linezolid is an oxazolidinone drug with a broad activity across *Nocardia* species (Table 137-2).[88] Linezolid has successfully treated nocardiosis alone or as part of combination therapy in case series of patients with TMP-SMX intolerance or allergy.[47,89] Due to its favorable in vitro susceptibility and high bioavailability, linezolid is a reasonable addition to empiric therapy while awaiting speciation and susceptibility data. Some clinicians prefer linezolid over amikacin in empiric therapy due to the more favorable side-effect profile of linezolid in the short term and its excellent CNS penetration. Use of linezolid (>2 weeks) can result in myelosuppression. Clinically, linezolid may be given twice a day then tapered to daily dosing due to the slow-growing nature of *Nocardia* and to minimize myelosuppression. In a retrospective review, linezolid-containing regimens (n = 20) and non-linezolid regimens (n = 8) were evaluated.[90] The median linezolid induction therapy duration was 28 days. The most common adverse effects in linezolid-containing regimens were thrombocytopenia (45%) and anemia (40%).[90] Adverse events prompting the discontinuation were more common due to TMP-SMX (40%) than linezolid (20%). There was no significant difference in 30-day mortality between the two treatment arms.[90] Other adverse events due to linezolid are serotonin syndrome with coadministration of selective serotonin reuptake inhibitors (SSRIs), peripheral neuropathy, and lactic acidosis. Tedizolid is a newer drug in the oxazolidinone class. In an in vitro susceptibility study, tedizolid had a MIC90 value two to three dilutions more active than linezolid for most *Nocardia* spp., with the exception of the *N. nova* complex and *N. brasiliensis*.[91] Tedizolid possesses a longer half-life, higher protein-binding capacity, and lower CNS penetration than linezolid. Tedizolid causes less myelosuppression and serotonin syndrome with coadministration of SSRIs compared with linezolid. A few case reports and a case series have demonstrated the effective use of tedizolid for nocardiosis treatment.[92–94]

Third-generation cephalosporins (ceftriaxone, cefotaxime, and cefuroxime) have variable activity against *Nocardia* species (Table 137-2) but a favorable side-effect profile and excellent CNS penetration. Several case reports have demonstrated successful combination therapy with ceftriaxone for the treatment of CNS nocardiosis.[95,96] Ceftriaxone, cefotaxime, and cefuroxime are reasonable therapies for *Nocardia* once susceptibility data are available.

Minocycline is the tetracycline with the best in vitro activity against *Nocardia* spp. Minocycline has been used in combination therapy.[45,97] However, treatment failure with minocycline has been described.[98] Minocycline is an option for cutaneous infection when TMP-SMX is not an option and susceptibility data are available. Minocycline toxicity includes photosensitivity, headache, nausea, dizziness, esophageal ulcerations, and skin changes with prolonged use.[99]

Amoxicillin-clavulanate provides moderate coverage against *Nocardia* spp., particularly *N. brasiliensis*. Amoxicillin-clavulanate is useful for the treatment of *Nocardia* spp. when susceptibilities are known.[100,101]

In vitro susceptibility of *Nocardia* spp. varies for tigecycline, fluoroquinolones (ciprofloxacin, levofloxacin, moxifloxacin), and macrolides (azithromycin, clarithromycin) (Table 137-2).[82] A few case reports mention successful therapy, but these agents are not first-line empiric therapies.[102–104]

Following empiric therapy, targeted antibiotic therapy guided by susceptibility data is recommended. Patients may be transitioned from parenteral to oral therapy after 3 to 6 weeks based on clinical improvement and antimicrobial susceptibility results. However, undrained abscesses and persistent necrotic areas often require prolonged parenteral antibiotics with radiographic monitoring. Decreasing immunosuppression when possible is an important adjunct to antibiotic therapy for all *Nocardia* infections. Surgical drainage may be necessary in the treatment of nocardiosis, particularly in cerebral and soft tissue abscesses refractory to antibiotic therapy. Pericardial effusions, mediastinal collections, and empyema secondary to pulmonary nocardiosis require drainage and antibiotic therapy. The risks and benefits of abscess drainage need to be considered. If drainage of the abscess is deemed unsafe, radiographic monitoring for resolution on antibiotic therapy is indicated.

■ Duration of Treatment

The duration of therapy has not been well studied. Therapy duration is based on the site of infection, host net state of immunosuppression, and clinical response to therapy (Table 137-4). In cutaneous nocardiosis in an immunocompetent host, antimicrobial therapy is recommended for 1 to 3 months.[6] Uncomplicated pulmonary infection in an immunocompetent host without neurologic involvement is treated for a minimum of 6 months. Patients with disseminated nocardiosis, CNS disease, and immunocompromised hosts with

TABLE 137-4 Estimated Recommendations for Duration of Treatment for Nocardiosis

Clinical Manifestations	Estimated Duration of Therapy
Pulmonary or systemic	
Immunocompetent	6–12 months[a]
Immunocompromised	12 months[b]
CNS disease and disseminated disease	12 months
Cutaneous	3 months
Osteomyelitis, arthritis, laryngitis, sinusitis	4 months
Mycetoma	6–12 months after clinical resolution

[a] *Depending on clinical response; for severe pulmonary infection or disseminated disease would recommend at least 12 months of therapy.*

[b] *HIV and CGD patients may be placed on secondary prophylaxis indefinitely.*

pulmonary infection are treated for a minimum of 12 months.[6] Common practice is to place HIV and CGD patients on secondary prophylaxis following *Nocardia* infection.

ACTINOMYCOSIS

Actinomycosis is an indolent infection caused by anaerobic or microaerophilic bacteria primarily belonging to the genus *Actinomyces*. The disease is marked by the formation of sinus tracts, granulomatous inflammation, and suppuration. The spread of infection with actinomycosis across tissue planes results in tract formation, and suppuration is notable for small yellow granules reminiscent of elemental sulfur. Actinomycosis may manifest as dense, "woody" lesions with surrounding fibrosis suggestive of malignancy. In its pulmonary manifestations, actinomycosis mimics several pathogens, ranging from fungal to mycobacterial to bacterial. Diagnosis is further complicated by the diversity of infection sites. Agents of actinomycosis are part of the human microbiota, colonizing the mouth, colon, and vagina, and often spread following trauma or insult. Growth on culture can sometimes be misinterpreted as normal flora. Prolonged antibiotic therapy is often curative.

History and Classification

Similar to nocardiosis, the causative agent of actinomycosis was first identified in cattle. Bollinger discovered a pathogen, later identified as *Actinomyces bovis*, as the cause of "lumpy jaw."[105] In 1878, James Israel described a case of actinomycosis in a human host.[106,107] This first case involved thoracic disease, which accounts for approximately 15% of all actinomycosis cases.[79] Due to the branching filamentous appearance of the organism, Dr. Israel and those who followed him for more than 70 years would incorrectly attribute the infection to a fungal pathogen—hence the misnomer *actinomycosis*, meaning "ray fungus." Although a bacterial etiology was established by 1957, reference to a fungal infection persisted in publication until at least 1975.[108] Actinomycosis is caused primarily by members of the genus *Actinomyces*. *Pseudopropionibacterium propionicum* (formerly *Propionibacterium propionicum* and *Arachnia propionica*) is an additional agent of actinomycosis.[109–111] Similar to *Nocardia* spp., *Actinomyces* spp. has undergone taxonomic changes resulting in the reclassification of some *Actinomyces* spp. to *Trueperella* (*Arcanobacterium*), *Actinotignum* (*Actinobaculum*), or *Cellulomonas*.[111–113] Currently, there are 26 published *Actinomyces* species recovered from human samples. *Actinomyces israelii* is the most common *Actinomyces* species isolated in human infection.[114] *A. israelii*, *A. gerencseriae*, *A. graevenitzii*, *A. meyeri*, *A. odontolyticus*, *A. turicensis*, *A. cardiffensis*, *A. funkei*, and *A. naeslundii* are associated with thoracic disease.[115,116]

Epidemiology

Actinomycosis was likely more common prior to the advent of antibiotics. Cope, in his seminal 1938 treatise *Actinomycosis*, stated that it "existed wherever there was a microscope and a laboratory."[117] However, studies of the prevalence of actinomycosis in the latter half of the 20th century indicate that while human colonization is nearly universal, progression to human disease is rare. A review of 57 cases at the University of Iowa over 36 years demonstrated a decrease in incidence of actinomycosis from 1:14,800 in the mid-1930s to 1:63,118 by the 1970s.[117] The incidence of actinomycosis in Germany and the Netherlands in the 1960s was estimated to be 1:100,000.[79] Recently, 71 consultations for actinomycosis were noted by the Department of Health in the United Kingdom from 2002 to 2003—an estimated 0.0006% of all consultations.[114] Among patients with pulmonary opacities, one series of 2247 Italian patients identified pulmonary actinomycosis in only 13 patients (0.6%).[118] Limited data exist regarding the presence of actinomycosis in low- and middle-income countries.

Disease Pathogenesis

A variety of virulence factors and host immune responses play a role in the pathogenesis of actinomycosis.

Virulence Factors

Actinomycetes are commensals, known to produce biofilms and fimbriae for attachment to the host as well as other organisms. Most clinically relevant species of *Actinomyces* can produce biofilms using polysaccharides of levan, dextran, glycogen, and *N*-acetylglucosamine.[119] In addition, they have both type 1 and type 2 fimbriae, made largely of shaft proteins FimA and FimP and cap protein FimB, each type with a separate purpose. Type 1 fimbriae adhere to proline-rich proteins that are found on the mineral surface of teeth,[120] while type 2 fimbriae use the shaft protein FimA to adhere to oral streptococci and host red blood cells, and to aid in biofilm formation. Variations in the expression of these two fimbriae affect the specific niche of a species—for example, *A. naeslundii* possesses fewer type 1 fimbriae and adheres preferentially to epithelial cells rather than dental surfaces.[121]

Host Immune Responses

Fimbriae enable *Actinomyces* to form dense clumps of "mycelial" growth, conferring protection against phagocytosis by neutrophils.[122,123] Additionally, clumping protects against antibiotics.[124] A phosphatase-driven inflammatory host response occurs at the site of growth, leaving calcium phosphate in the center of this mass, thus a mineralized granule core. Histologically, these appear as rosettes of branching filaments, from 30 to 400 μm in size, with radial clubbing at the periphery, which results from filaments being covered in protein-polysaccharide complexes. Foamy macrophages play a role in host response, causing the yellow coloration of the "sulfur granule."[125] Actinomycosis commonly presents as a polymicrobial infection, believed to enhance pathogenesis.[116] As an example, *A. viscosus* alone produces inflammation through activation of Toll-like receptor 2, but it gains resistance to phagocytosis and killing by neutrophils when coaggregated with *Streptococcus mitis*.[126,127]

Risk Factors for Disease

Actinomycosis typically occurs in individuals 20 to 60 years of age and is three times more common in men than women.[114] Alcoholism is associated with actinomycosis, likely due to an increased aspiration risk.[128] Pulmonary actinomycosis is more prevalent in individuals with chronic lung diseases like bronchiectasis, chronic bronchitis, and emphysema.[128] Trauma, surgery, dental procedures, and dental sepsis disrupt the mucosal barrier and increase the risk of actinomycosis.[129] Additionally, osteoradionecrosis and bisphosphonate-related osteonecrosis of the jaw disrupt bone and tissues in the cervicofacial region and are associated with actinomycosis.[116] Several case reports describe the association with hereditary hemorrhagic telangiectasia and the occurrence of *Actinomyces* spp. and polymicrobial brain abscesses (Fig. 137-7).[116] Other risk factors for actinomycosis include diabetes, HIV, leukemia with chemotherapy, solid-organ transplantation, and corticosteroid use.[114,116]

Clinical Manifestations

Actinomycosis is divided by anatomic location: thoracic (15%–20%), cervicofacial (50%), and abdominopelvic (20%) are the most common presentations.[105] Less common infections involve the CNS, musculoskeletal system, prosthetic joints, ophthalmic infections, cutaneous infections, and disseminated disease.[114,128]

Thoracic Actinomycosis: Pathogenesis and Clinical Presentation

Aspiration of oropharyngeal secretions is considered the primary mechanism for thoracic actinomycosis. Thoracic disease due to

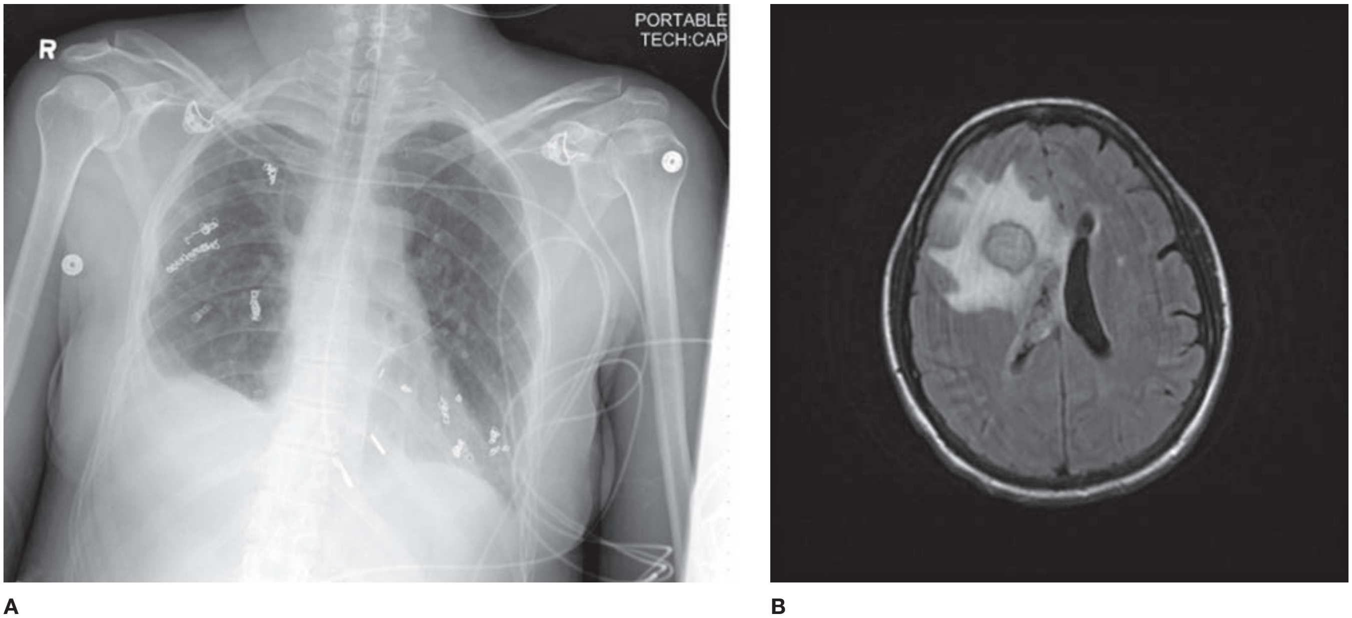

Figure 137-7 CNS polymicrobial abscess (including *Actinomyces* spp.) in a 53-year-old female with past medical history of hereditary hemorrhagic telangiectasia, right lung resection, and coiling of pulmonary arteriovenous malformations (AVMs), who presented with fever, altered mental status, and symptoms of meningismus. **A.** Chest x-ray shows evidence of a prior right lung resection and multiple bilateral coils over the chest representing sequelae of prior AVM procedures. **B.** Axial MRI FLAIR image of the brain demonstrates a right frontal lobe periventricular abscess with surrounding white-matter edema producing mass effect on the anterior horn of the right lateral ventricle. The patient underwent a craniectomy and external ventricular drain placement, and cultures grew *Actinomyces* spp., *Haemophilus aphrophilus*, and α-hemolytic *Streptococcus*.

direct spread of cervicofacial or abdominopelvic disease was more common prior to the advent of antibiotics but is rare in the modern era.[128] Thoracic actinomycosis is subdivided into pulmonary, pleural, mediastinal, chest wall, and mixed presentations. Pulmonary disease is the most common form of thoracic disease. Symptoms can mimic tuberculosis, malignancy, fungal infection, and other chronic pneumonias (Table 137-5). Symptoms of pulmonary actinomycosis include cough with or without sputum production, shortness of breath, chest pain, and hemoptysis, and may be associated with fever, night sweats, weight loss, and fatigue (Table 137-6). While these symptoms are common in many pulmonary infections, a hallmark of pulmonary actinomycosis is clinical improvement with standard community-acquired pneumonia treatment followed by recrudescence of infection days to weeks following cessation of antibiotics.

Actinomycosis can spread from the lung parenchyma contiguously to the pleura, mediastinum, and chest wall. Such intrathoracic spread should suggest the diagnosis of actinomycosis. Empyema necessitans, in which an empyema extends outward through the chest wall, is rare as antibiotics are often given prior to progression of infection. Esophageal perforation resulting in mediastinitis is a less common cause of thoracic disease.[114] Additionally, *Actinomyces* spp. are a rare cause of breast abscesses, as described in several case reports.[130,131]

Thoracic Actinomycosis: Radiographic Presentation

Parenchymal actinomycosis manifests as pulmonary consolidations (36%–100%) and masses or nodules (9%–48%) (Table 137-7).[132–135] In early stages of infection a small peripheral nodule occurs, which gradually progresses into a consolidation or mass (Fig. 137-8).[136] The consolidation often contains hypoattenuated areas with cavitation. Pleural thickening near the site of parenchymal infection is present in many patients (24%–100%).[132–135] On chest CT, bronchiectatic actinomycosis appears as a localized bronchiectasis, irregular bronchial wall thickening, and peribronchial consolidation.[137] Parenchymal and bronchiectatic actinomycosis may occur simultaneously in some patients. Endobronchial actinomycosis is rare and due to colonization of foreign bodies or obstructive broncholiths, formed by erosion of calcified lymph nodes into the airway due to a granulomatous process.[137] Endobronchial actinomycosis secondary to a broncholith appears on chest CT scan as a proximal obstructive calcified endobronchial nodule with distal obstructive pneumonia.[137] Fluorodeoxyglucose positron emission tomography (FDG-PET) imaging findings may be nonspecific, as actinomycosis can be hypermetabolic on this imaging modality.[79]

A fungus ball appearance is a well-documented but less common radiographic presentation. Actinomycosis in this form is often diagnosed invasively, by lobectomy, video-assisted thoracoscopic surgery, and bronchoalveolar lavage.[138]

The more specific and classically described finding of rib destruction is rare in the modern antibiotic era—occurring only 2 times in 94 patients among 4 case series dating from the 1970s to 2010,[133,135,139–141] with both occurrences in older series from 1974 and 1990.[139,140] Chest wall invasion, another classically described finding of actinomycosis, is uncommon.

Cervicofacial Actinomycosis

The loss of mucosal integrity following facial trauma, dental manipulation, poor dental hygiene, or necrosis following medications such as bisphosphonates transforms commensal agents of actinomycosis into opportunistic pathogens, resulting in cervicofacial disease (Fig. 137-9). Oral disease is predominated by *A. israelii*, *A. gerencseriae*, and *A. naeslundii/viscosus*, which were associated with 75% of cases in one large series.[142] Coinfection with other pathogens is common. Cervicofacial actinomycosis manifests as soft tissue swelling around the mandible and potential progression to dense "woody" induration, with or without pain. Oral actinomycosis presents as ulcerations, abscesses, and nodules resembling malignancy, and biopsy is often necessary for diagnosis.[143] Sinus tracts and

Radiographic						
	Nodules, cavitation, diffuse infiltrates, pleural effusions	Consolidation, nodules, masses, cavities, across tissue planes (interlobar extension, empyema, mediastinitis, pericarditis)	Diffuse miliary nodules, eventual cavitation	Lobar infiltrates that can lead to nodules, cavitation, pleural effusion	Reactivation TB more common in upper lobes, cavitation	Cavitary upper lobe disease, nodules
Laboratory Diagnosis						
Gram stain	Gram-positive filamentous rods, weakly acid fast	Gram-positive filamentous rods, not acid fast	Gram-negative rod, sometimes bipolar staining	Gram-positive coccobacillus, slightly acid fast	Gram-neutral, acid fast	Gram-neutral, acid fast
Culture media	Standard media, BCYE media, selective media (Thayer–Martin)	Anaerobic (*A. meyeri* and *A. neuii* can grow aerobically)	Routine (e.g., blood agar, MacConkey)	Routine (e.g., blood agar) aerobic culture	Solid (e.g., Lowenstein–Jensen) or liquid media	Solid (e.g., Lowenstein–Jensen) or liquid media
Culture time	48 h–14 days	Usually 5–7 days, but may take 4 weeks	Usually within 48 h	Usually within 48 h	4–8 weeks on solid media, 6–10 days in liquid media	On solid media, 2–6 weeks
Other diagnostic methods	NAAT, MALDI-TOF	Sulfur granules 16S sequencing; MALDI-TOF databases still being optimized	Fluorescent antibody, agglutinin antibody, NAAT	Biochemical tests, NAAT	Tuberculin skin test, IFN-γ release assay, NAAT	NAAT
Treatment						
Pharmacologic	Sulfonamides first line, often require two agents	Penicillin first line, resistance very rare	Carbapenems, ceftazidime, trimethoprim-sulfamethoxazole	Vancomycin, fluoroquinolones, rifamycins, macrolides, sulfonamides, aminoglycosides	Rifampin, isoniazid, pyrazinamide, ethambutol (resistant strains require additional antibiotics)	NTM susceptibility–guided therapy MAI: rifampin + ethambutol + macrolide

NTM, nontuberculous mycobacterium; IC, immunocompromised; CKD, chronic kidney disease; ESRD, end-stage renal disease; COPD, chronic obstructive pulmonary disease; CF, cystic fibrosis; BCYE, buffered charcoal–yeast extract agar; MAI, Mycobacterium avium-intracellulare; NAAT, nucleic acid amplification test.

trismus can occur; infection can spread to local structures, resulting in periostitis or osteomyelitis, observed in 12% of patients in a review of 317 cases.[114] Newer radiographic techniques have been proposed to help differentiate actinomycosis from some of its mimics and monitor the response to therapy. F-alpha-methyl tyrosine PET/CT and quantitative light-induced fluorescence are both used in cervicofacial disease, but not widespread in clinical practice.[144,145]

Abdominopelvic Actinomycosis

Abdominal actinomycosis results from mucosal disruption due to abdominal surgery, trauma, neoplasm, ingestion of a foreign body, or perforated viscus (Fig. 137-10). Appendicitis is the most common presentation of abdominal actinomycosis, associated with 65% of cases. Dropped gallstones during cholecystectomy are another possible source of infection.[146] Despite the high incidence of diverticulitis, only a small

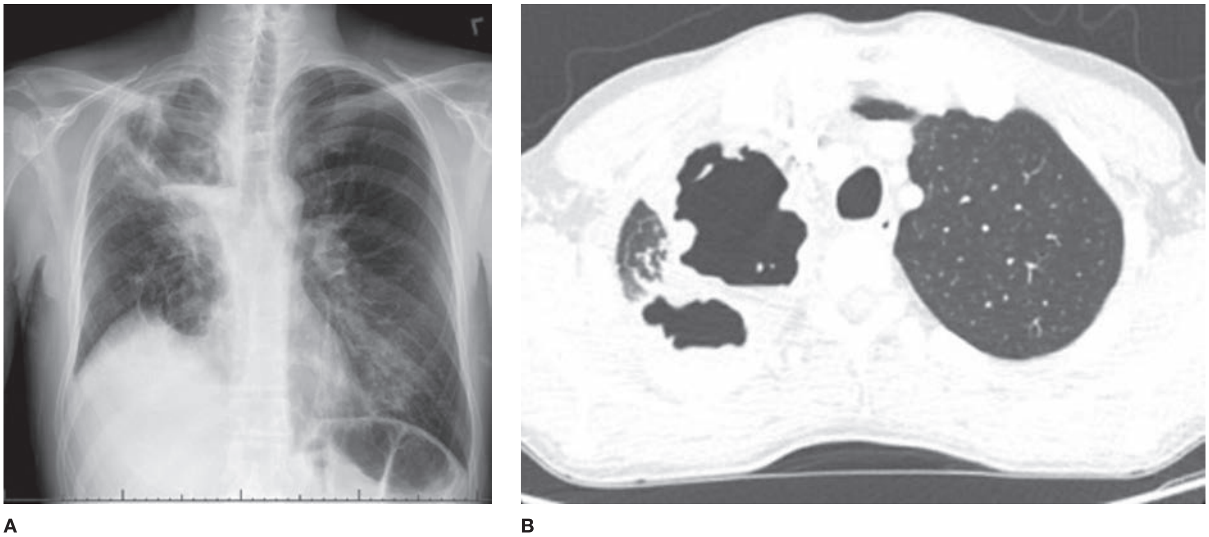

Figure 137-8 Pulmonary actinomycosis infection concurrent with squamous cell lung carcinoma in a 50-year-old male. **A.** Frontal chest x-ray shows right lung volume loss and a loculated hydropneumothorax suggesting recent lobectomy. The patient underwent right upper lobe lobectomy 4 weeks prior for a 10-cm mass shown to be squamous cell carcinoma. **B.** Axial CT of the chest confirms the presence of a loculated cavity with irregular thickened septations in the right apical lung. A right-sided chest tube drained 10 cc of pus, which grew *Actinomyces odontolyticus*.

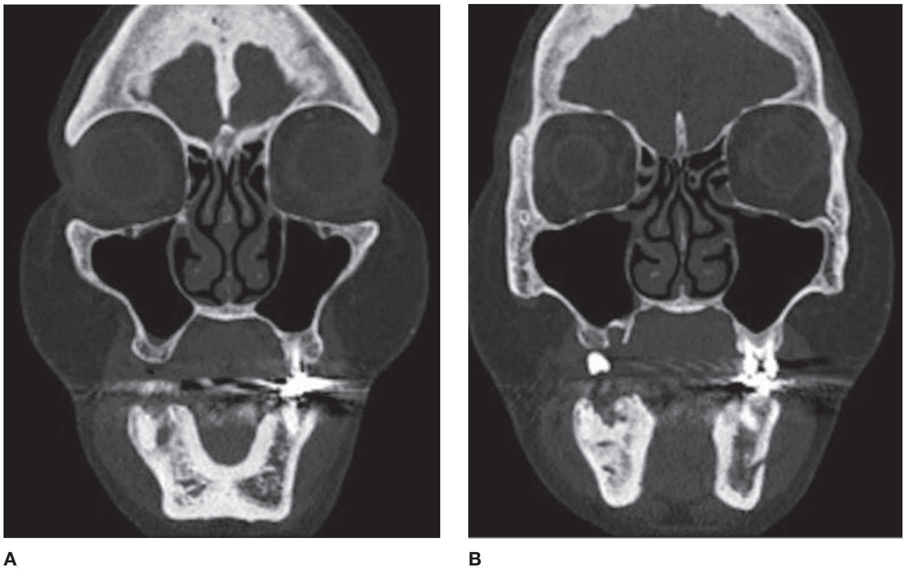

Figure 137-9 **A** and **B.** Mandibular osteomyelitis secondary to actinomycosis in a 76-year-old female with past medical history of diabetes mellitus who underwent extensive dental work prior to developing right mandibular pain. She underwent a bone biopsy with pathology consistent with osteomyelitis, and multiple cultures were significant for *Actinomyces* spp. and *Prevotella/Porphyromonas*. Coronal CT maxillofacial images show asymmetric cortical thickening and sclerosis of the right mandible and erosions in the visible tooth bed, suggesting a clinical diagnosis of osteomyelitis.

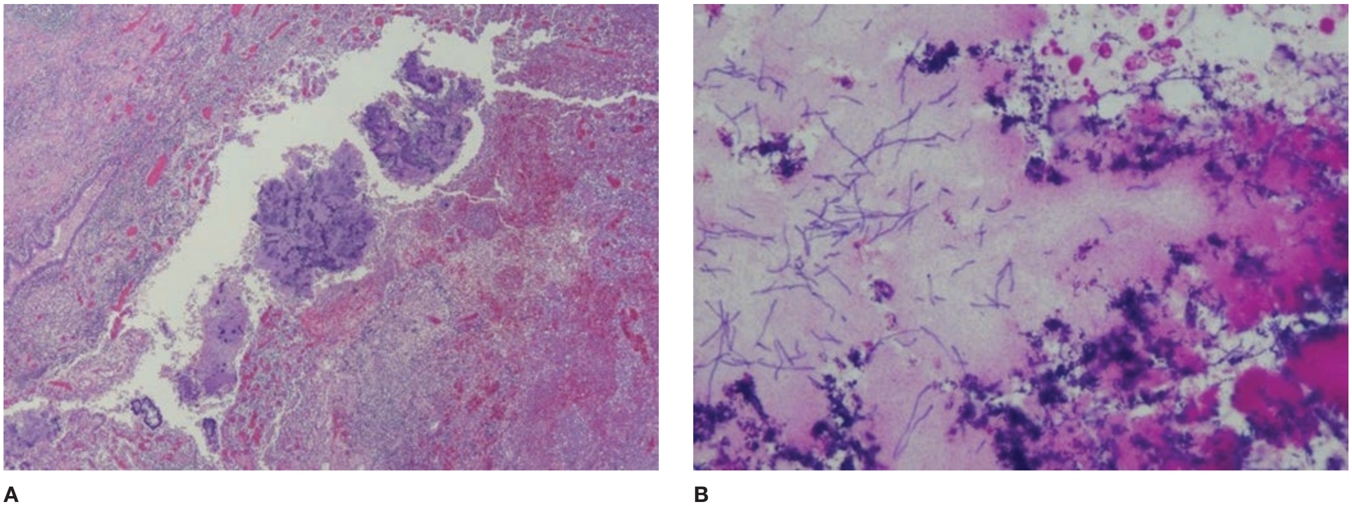

Figure 137-10 Histopathology of actinomycosis. **A.** Granules of thoracic actinomycosis (hematoxylin-eosin, 10×). **B.** Same thoracic granule showing mixed bacterial morphologies including *Actinomyces* spp. (Brown-Hopps, 100×). *(Reproduced with permission from Dr. Dominick Cavuoti.)*

number of cases result in abdominal actinomycosis. Diverticulitis and foreign body perforation between the distal colon and the hepatic flexure account for approximately 7% of cases. Sinus tract formation may occur through the abdominal wall and in the perirectal area. Anorectal disease presents as rectal strictures, perirectal abscess, and fistulous tracts.[129] Although gastric, hepatic, splenic, and renal disease are uncommon, actinomycosis spreads throughout the peritoneum and has the ability to seed any organ within the abdomen.[129]

Abdominal actinomycosis presents with fever, weight loss, constipation, and abdominal pain. The indolent nature of abdominal actinomycosis and vague symptomatology present a diagnostic challenge. In a review of abdominal actinomycosis (n = 406), diagnosis was obtained post-laparotomy in 91% of cases. The colon, abdominal wall, and appendix were the most involved structures, while the clinical presentation of a localized mass or malignant neoplasm occurred in 39% and 19% of cases, respectively. Despite frequent and early surgical intervention, average time to diagnosis for abdominopelvic actinomycosis was 10.6 days, even in a high-resource setting.[79,114,129,147]

Pelvic actinomycosis is most commonly associated with contraceptive intrauterine devices (IUDs), although any disruption of the uterine mucosa can serve as an inciting event, including pessaries, endometrial curettage, and surgical mesh placement. The risk increases with time from implantation of a foreign body; when actinomycosis arises in the setting of an IUD, it is on average at 8 years following IUD placement. In primary pelvic actinomycosis, infection spreads to the endometrium and ovaries. As with other forms of actinomycosis, patients present with indolent, nonspecific symptoms such as fever, localized pain, and weight loss. Abnormal vaginal bleeding is an additional symptom. If pelvic dissemination of infection occurs secondary to abdominal ileocecal disease, the ovary is the most commonly affected pelvic organ followed by the fallopian tubes, uterus, vulva, and cervix.[129] Differentiating colonization and infection is necessary, as *Actinomyces*-like organisms are found in 7% of Papanicolaou smears, and in the absence of infectious symptoms, these organisms should be considered as commensals in the female genitourinary tract.[79,114,129,148]

Other Forms of Actinomycosis: CNS infection, Otitis Media, Lacrimal, and Others

Central nervous system infections, while rare, can be fatal. The majority of CNS actinomycosis infections present as brain abscesses (75%) (Fig. 137-7), with a predilection for the frontal and temporal lobes.[131] CNS infection is typically associated with hematogenous spread from pulmonary, cervicofacial, and abdominal/pelvic infection. Consequently, headache and focal neurologic signs are the most common presenting symptoms. In a review of CNS actinomycosis cases (n = 70), the clinical manifestations reported were brain abscess (67%), meningitis and meningoencephalitis (13%), actinomycoma (space-occupying lesion) (7%), subdural empyema (6%), and epidural abscess (6%).[149] The primary foci of infection (n = 47) were identified as pulmonary (27%), cervicofacial (20%), abdominal pelvis (10%), and ear/mastoid and sinuses (10%).[149] Mixed bacterial infection was found in 34% of cases with available microbiologic culture data (n = 50).[149]

Lacrimal canaliculitis, musculoskeletal disease, and disseminated actinomycosis are other clinical manifestations of actinomycosis.[79,129,149]

■ Diagnosis: Microbiologic and Pathologic

Clinically and radiographically, actinomycosis is difficult to differentiate from more common pathogens. Traits of this pathogen are the indolent and refractory nature of the infection, failure to respond to shorter courses of antibiotics, and the anatomic progression across tissue planes and compartments. Consequently, regardless of the location, the key to management of actinomycosis is to consider the diagnosis and obtain microbiologic bacterial aerobic/anaerobic cultures from the infected site as well as consideration of tissue biopsy when possible. Microbiologic diagnosis is challenging, as agents of actinomycosis are highly sensitive to a wide variety of antibiotics and are commensals of the human respiratory, gastrointestinal, and genitourinary tracts, such that they may be considered and reported as normal flora by the laboratory. Evaluating a patient prior to antibiotic administration, if appropriate, increases the likelihood of obtaining a microbiologic diagnosis, as sputum samples and bronchial alveolar lavages can be rendered sterile with a single dose of antibiotics (although the underlying infection remains active).

Tissue biopsy with histopathologic diagnosis is often indicated and helpful, particularly if sulfur granules are found. A survey of 181 cases of actinomycosis found an average of 7 granules per specimen.[150] One to 3 granules were found in 56% of cases, while a single granule was identified in 26% of cases.[150] However, granules are not pathognomonic for actinomycosis, as they can be seen in nocardiosis, aspergillosis, and botryomycosis among others. To help differentiate, the agents of actinomycosis can be seen at the periphery of granules on hematoxylin-eosin stains as well as Grocott-Gomori methenamine silver or Giemsa stains, appearing as Gram-positive, filamentous, branching bacteria (Fig. 137-11).[79,114,129]

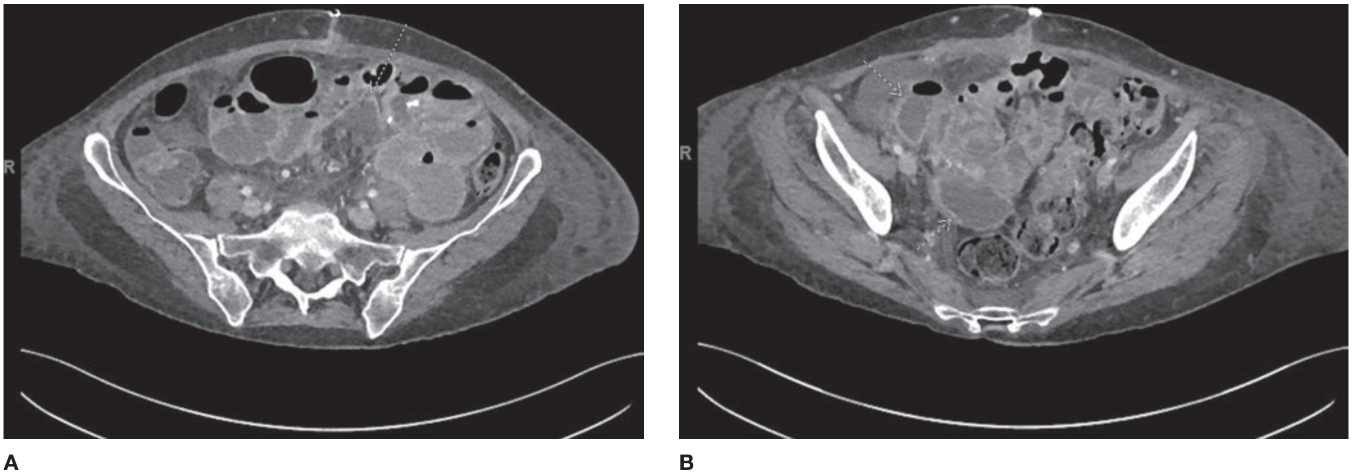

Figure 137-11 Abdominal actinomycosis in a 55-year-old female with a past medical history of diffuse large B-cell lymphoma refractory to chemotherapy, and history of multiple intra-abdominal surgeries, who presented with abdominal pain and underwent an open small bowel resection for bowel obstruction. Her course was further complicated by abdominal and pelvic abscesses. **A.** Axial CT of the abdomen shows a rim-enhancing 2.5-cm fluid collection with a collection of air between loops of bowel. **B.** Axial CT of the pelvis with multiple fluid collection; the largest is a 5 × 3 cm deep fluid collection with rim-enhancing walls. Her pelvic abscess was aspirated and grew *Actinomyces* spp. *(Reproduced with permission from Sally Chuang, MD.)*

Although low-yield in prior series,[151] larger and more recent case series have shown success with bronchoscopic biopsy and percutaneous thoracic needle biopsy/aspiration.[152]

An analysis of 11 case series from 1982 to 1999 demonstrated a gradual shift in diagnostic methodology. Prior to 1995, diagnosis of thoracic actinomycosis was 22% by nonsurgical means (fine-needle aspiration, bronchial biopsy) and 77% with surgical intervention. After 1995, this shifted to 47% by nonsurgical means and 53% by surgical means.[128] More recent cases demonstrate diagnosis via bronchial brush sampling,[153] transbronchial biopsy,[154] bronchoalveolar lavage,[155] bronchial alveolar lavage cytology in combination with transbronchial biopsy,[156] and transbronchial biopsy using a Wang needle for aspiration.[157]

16S rRNA nucleic acid amplification tests (NAAT) and MALDI-TOF are newer technologies that may enable detection of pathogens. However, their increased use has led to new challenges. Gram-positive rods in blood cultures that are true agents of actinomycosis but may previously have been considered as contaminants (i.e., presumed to be *Corynebacterium* spp. or *Propionibacterium* spp.) with NAAT and MALDI-TOF are now being identified on blood cultures. Although previously thought to always signal infection when found in sterile samples, a series of 60 patients with *Actinomyces* spp. found in blood culture showed no ill effect in withholding treatment for actinomycosis from 50 of those patients who were not felt to have risk factors for actinomycosis or symptoms.[158] What remains unknown is whether those isolates represented contamination (which might suggest a previously unknown dermatologic niche for *Actinomyces* spp. [via the site of puncture for blood cultures drawn through the skin]), or a transient, harmless bacteremia, which could be possible given that they are commensals in the oropharynx.[79,158]

■ Treatment

Penicillin is the treatment of choice for actinomycosis. Traditional therapy for actinomycosis is high-dose IV penicillin at 18 to 24 million units daily for 2 to 6 weeks, followed by oral penicillin or amoxicillin for a period of 6 to 12 months. In the setting of copathogens, many of which are anaerobic, the addition of a β-lactamase inhibitor to penicillin (e.g., ampicillin-sulbactam) is often used. If the patient is penicillin allergic, erythromycin, doxycycline, minocycline, and tetracycline are well-studied treatment options (Table 137-8). Clindamycin resistance is reported, with rates as high as 30% or greater.[159] Among other β-lactams, ceftriaxone, ertapenem, and imipenem-cilastatin have been used successfully although less frequently.[160–163] Metronidazole and moxifloxacin, both used for anaerobic infections, should not be used against actinomycosis due to high levels of resistance.[79,159,162,164]

Medical therapy is often curative. Adjunctive surgical interventions are dependent on the site, extent, and severity of infection. Surgery or percutaneous drainage is often indicated for infections within confined and critical spaces, such as the brain or epidural space, hemoptysis that cannot be managed otherwise, abscesses, extensive disease, or infection refractory to treatment. Medical failure occurs secondary to coincident pathology such as malignancy, tuberculosis, or aspergillosis. Drainable fluid collections should be aspirated and cultured, to expedite clinical improvement and identify copathogens for guidance of therapy. In the setting of an IUD infection, antimicrobial therapy and removal of the IUD are recommended.

TABLE 137-8 Treatment for Actinomycosis[a]

Extensive Clinical Experience and Success[a]	Anecdotal Experience and Success	Predicted Efficacy Based on In Vitro Activity
Penicillin	Ceftriaxone	Vancomycin
Amoxicillin	Ceftizoxime	Linezolid
Erythromycin	Imipenem-cilastatin	Quinupristin-dalfopristin
Tetracycline	Piperacillin-tazobactam	Rifampin
Doxycycline		Ertapenem
Minocycline		Tigecycline
Clindamycin[b]		Azithromycin

[a] *Additional coverage for concomitant bacteria may be indicated.*

[b] *Recent in vitro data demonstrated a >30% resistance rate.*

Data from Bennett JE, Dolin R, Blaser MJ: Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases, 9th ed. Philadelphia, PA: Elsevier/Saunders; 2020.

Duration of Treatment

Treatment duration should be individualized, and extension of therapy beyond 1 year may be indicated in complicated cases and immunocompromised hosts. Short courses of treatment have been used successfully with less extensive cervicofacial disease.[165,166] While some patients with complicated thoracic disease require longer courses, there are reports of shortened treatment courses. In a survey of 19 patients with thoracic actinomycosis, radiographically, pulmonary disease was reported as unilateral in 12 cases and bilateral in 1 case; cavitation occurred in 3 cases and pleural abnormalities were present in 7 cases. Two patients experienced extrapulmonary complications, including vertebral bone erosion and liver abscess.[140] All 19 cases were successfully treated with a median duration of 6 weeks (range, 1–24 weeks) of antibiotic therapy, and 7 patients underwent surgical resection.[140] In a series of 28 patients with thoracic actinomycosis, radiologic findings included consolidation (61%), nodular or masslike lesions (32%), and atelectasis (7%); 96% of these cases were successfully treated.[167] In solely medically managed individuals (n = 15), IV antibiotic therapy was administered for a median of 2 days (range, 0–18 days) and oral antibiotic therapy lasted a median of 167 days (range, 76–412 days). In patients who received a combination of antibiotic and surgical treatments (n = 13), IV antibiotic therapy was administered for a median of 8 days (range, 3–17 days) and oral antibiotic therapy lasted a median of 150 days (range, 0–534 days).[167] Shortened courses of antibiotic therapy should be approached with caution in patients with thoracic disease who have not had surgical debridement given the risk for relapse of infection.[168]

Conclusion

Nocardiosis and actinomycosis are rare infections often termed "the great masqueraders" due to their variable presentations and similar clinical manifestations to other infectious diseases. Microbiologic diagnoses are challenging, but with advances in molecular methodologies, the identification of these organisms is improving. Despite the low incidence of nocardiosis and actinomycosis, awareness of these infections, early diagnostic consideration, and initiation of appropriate treatment allow for more favorable outcomes. Due to the complexity of these infections and considerable duration of management, an infectious disease consultation, if available, is recommended.

CHAPTER 138

Zoonotic and Environmental Bacterial Pneumonias

Camille Nelson Kotton
Howard M. Heller

INTRODUCTION

Many different microorganisms can infect the lung parenchyma; the focus in this chapter is pneumonias caused by zoonoses, environmental pathogens, and other unusual bacterial pathogens. Making a clinical diagnosis of pneumonia is relatively easy; defining the causative agent can be difficult. Routes of spread to the lungs are few, clinical presentations overlap, radiologic appearance often is nonspecific, and pathophysiologic mechanisms are limited. The search for the specific etiologic agent is driven by the desire to administer a specific antimicrobial drug as soon as possible, hopefully avoiding progressive functional impairment and containing spread to other individuals or to a community. Identifying a pathogen may, in turn, expand epidemiologic considerations and public health awareness.

In the decades that have passed since the epidemic of acute respiratory "Legionnaire's disease" due to *Legionella* erupted among delegates to the American Legion Convention in Philadelphia in 1976, physicians, microbiologists, and epidemiologists have become increasingly prepared for the diagnostic challenges of patients with unusual pneumonias. Some newer zoonotic pathogens with primarily pulmonary manifestations include Sin Nombre virus (hantavirus pulmonary syndrome) and certain coronaviruses (Chapter 126). Zoonotic viral pathogens that can be transmitted from animal to human, and then human to human, including influenza and the coronaviruses, have the greatest potential for rapid pandemic spread; it is likely that new viral respiratory pathogens will continue to emerge. Viral pathogens are discussed in detail elsewhere; the focus of this chapter is exclusively bacterial pathogens most often associated with animals, animal products, or the environment.

Global surveillance and cooperation have enabled more rapid recognition of new infectious syndromes, and the use of molecular techniques has allowed for rapid development of diagnostic tools that are critical for understanding the animal origin of pathogens and routes of transmission. Zoonotic infections can reflect an initial event, followed by person-to-person secondary cases, typical of viral diseases like the severe acute respiratory syndrome coronaviruses (SARS-CoV-1 and SARS-CoV-2) and occasionally observed with *Yersinia pestis*. While avian influenza virus (H5N1) primarily spread to individuals in proximity to chickens, the novel H1N1 influenza virus in 2009–2010 demonstrated an anthropocentric cycle that led to a worldwide pandemic, despite being of zoonotic origin. New zoonoses are always emerging: an outbreak in a monkey colony of deadly titi monkey adenovirus, not known to infect humans, was shown to infect a researcher and a family member, without further spread.[1] Similarly, *Streptococcus equi* subsp. zooepidemicus (*Streptococcus zooepidemicus*)[2] has been shown to cause pneumonia in humans after exposure to horses, dogs, and unpasteurized milk.

Companion animals have been the source of numerous zoonotic pneumonias, including *Pasteurella multocida*,[3,4] *Chlamydia psittaci*,[5] *Rhodococcus*, and *Bordetella bronchiseptica* hosts[6–9] (Tables 138-1 and 122-5). In a study in Spain, contact with pets was associated with an increased risk for community-acquired pneumonia, which tended to be more frequent as the number of pets increased; the relative risk was similar for bird, cat, and dog exposures.[10] There are multiple examples of animals serving as reservoirs of antibiotic-resistant bacteria, such as methicillin-resistant *Staphylococcus aureus* (MRSA) (companion animals,[11,12] pigs[13]); some are seen in association with nosocomial ventilator-associated pneumonia[11] and highly resistant Enterobacteriaceae.[14] Nonetheless, experts usually permit companion animals for even immunocompromised hosts, balancing the risk of infection with benefit.[6,15] Wild and farm animals may also harbor zoonotic pneumonia pathogens. *Pasteurella multocida* has been associated with pneumonia in bighorn sheep,[16] lambs,[17] and pigs.[18] *Yersinia pestis* has been associated with numerous wild mammals; recent work suggests a correlation between seropositivity in coyotes and human disease.[19]

Many of the zoonotic bacteria discussed in this chapter are recognized as pathogens that can be weaponized for use by terrorist organizations. The global community is developing rapid diagnostics and countermeasures to warn, protect, and treat people exposed to a biologic weapon. Unfortunately, we have the experience of the "mailroom" anthrax event of September 2001 to illustrate the potential of an inhalational disease causing illness, casualties, public panic, and challenging diagnostic and therapeutic decisions, as well as the expenses of decontamination and task of criminal investigations.[20] Physicians need to become familiar with the typical and atypical spectrum of disease caused by these pathogens, including the impact and variable expression of a large inoculum aerosol release in a crowded urban area or building.

This chapter focuses on the epidemiologic and clinical features helpful in evaluating typical and atypical features of zoonotic and environmental bacterial pneumonias (Table 138-1). The unique properties of these bacteria exemplify how bacteriology, molecular biology, ecology, epidemiology, and pathogenesis serve as clues to earlier etiologic diagnosis and to initiation of specifically targeted therapies. The movements of immigrant populations, adventure and other forms of travel, the immune status of individuals, the latency of pathogens, and the legal and illegal transportation of live animals and animal products contribute to the importance of zoonotic pneumonias. Ultimately, the diagnosis is heavily dependent on a detailed history, along with appropriate diagnostic studies.

ZOONOTIC BACTERIAL PNEUMONIAS

Several important diseases are spread to humans predominantly from animal contact, including pasteurellosis, plague, tularemia, and *Rhodococcus*. The diagnosis usually depends on a careful animal exposure history. Once alerted, the clinician can request appropriate studies, as these diseases may be more elusive in their diagnosis.

■ *Pasteurella multocida*

P. multocida is a common commensal of the oral cavity of most felines and many dogs and a frequent respiratory pathogen in animals and birds.[3] The respiratory tract is the second most common site of *Pasteurella* infection, following skin and supporting tissues. Elderly people with structural lung diseases, such as emphysema, bronchiectasis, or malignancy, are at higher risk for pulmonary infection.[21,22] Immunocompromised patients, including those with AIDS, may be prone to infection without close contact or traumatic dog or cat exposures. Immunosuppressing medications, including TNF inhibitors and interleukin 6 blockers, also may increase risk.[23,24] Pneumonia caused by the closely related organism *Pasteurella canis* has been reported.[25]

TABLE 138-1 An Overview of Zoonotic and Other Unusual Pneumonias

Environmental Niche	Microorganism	Disease	Epidemiologic Associations	Distribution
Live animal contact or via arthropod	*Chlamydia psittaci*	Psittacosis	Inhalation of bird respiratory secretions or feces.	Worldwide
	Francisella tularensis	Tularemia	Contact with wild and pet animals, birds, or arthropods (ticks, deer fly)	North America, Europe, Asia
	Pasteurella multocida	Pasteurellosis	Feline and dog contact; chronic lung disease	Worldwide
	Rhodococcus equi	Rhodococcus pneumonia	Airborne droplets; contact with soil contaminated with horse, cow, or swine excrement	Worldwide
	Yersinia pestis	Plague	Contact with rodents, fleas; contact with plague pneumonia case	Worldwide, including Asia, southwest U.S.
Soil, stagnant water, and inert animal products	*Bacillus anthracis*	Inhalation anthrax or woolsorter's disease	Industrial; use of or contact with animal products in hobbies	Worldwide in warmer regions inhabited by grazing animals
	Brucella species	Brucellosis	Ingestion or contact with infected animal products, slaughterhouses	Worldwide
	Burkholderia pseudomallei	Melioidosis	Direct penetrating contact of wounds with soil, water	Latitude 20°N to 20°S, especially rural Asia, northern Australia
	Coxiella burnetii	Q fever	Contaminated birthing products, milk, meat, and wool, or inhalation of windblown dust from areas contaminated by placentae and other animal product	Worldwide

Bacteriology

P. multocida is a small, Gram-negative, bipolar-staining coccobacillary organism that resembles *Haemophilus* spp. and may form pairs and chains. Rapid growth on blood agar and inhibition by MacConkey medium separate this microorganism from other common components of the respiratory flora, including *Haemophilus* spp. Numerous virulence factors in *P. multocida* have been identified. These include the capsule in serogroups A and B (which interferes with phagocytosis), a toxin in strains causing atrophic rhinitis in pigs, lipopolysaccharide endotoxin, several iron acquisition proteins (e.g., TonB, ExbD, ExbB), and the putative filamentous hemagglutinins PfhB1 and PfhB2.

Ecology, Epidemiology, and Pathogenesis

In cats and other felines, the organism resides periodontally in the anterior regions of the mouth. Isolates from dogs are characteristically from the posterior pharynx. Many birds and domestic and wild animals worldwide harbor this organism as a commensal in oral or gastrointestinal areas. *P. multocida* is occasionally found in the secretions of persons with chronic lung disease, especially those with bronchiectasis and domestic animal contacts. Cooking and ingestion of pig trotters (feet) as well as occupational exposure in an abattoir worker with subsequent pneumonia have been described.[26,27] Human-to-human transmission has been documented from mother to newborn infant, resulting in neonatal pneumonia. The organism can survive in soil and water for more than 3 weeks and in animal carcasses for approximately 2 months. In about half of the cases of respiratory disease, no clue to airborne spread exists, but there are usually cats in the local environment.

Pathogenic strains have a polysaccharide capsule that inhibits phagocytosis, and an endotoxin is contained within the cell envelope. Exotoxins and other pathogenicity-promoting factors have not been specifically identified (see "Bacteriology," below). Almost all patients who develop respiratory infections have underlying chronic pulmonary disease. Aspiration probably initiates active infection. Necrosis and lung abscess, empyema, septicemia, and transbronchial spread to other lung segments have been described.

Clinical and Radiologic Features

The clinical features of *P. multocida* respiratory disease include worsening of the patient's baseline pulmonary function—especially when high fever, tenacious secretions, and pleural effusions develop. Radiologic changes include lobar, multilobar, or diffuse patchy infiltrates, usually sparing the upper lobes, superimposed on underlying chronic lung disease (Fig. 138-1). Pleural effusions and empyema have been noted in approximately 20% of cases. Bacteremia has been reported in up to 55% of patients with pneumonia, and endocarditis has occasionally complicated bloodstream invasion.[3,28]

Diagnosis and Differential Diagnosis

Diagnosis depends on isolation of the organism from sputum, pleural fluid, or blood. Usually, the pathogen can be identified with the routine methods of the diagnostic laboratory. The bipolar, Gram-negative–staining bacilli resemble *Brucella* spp., *Y. pestis*, *Francisella tularensis*, *Burkholderia pseudomallei*, and *Haemophilus* spp., but the clinical history of exposure to cats and/or dogs and bacteriologic characteristics can rapidly clarify identification.

Treatment

Most strains are exquisitely susceptible to penicillin or ampicillin. Third-generation cephalosporins are as active as penicillin and more potent than earlier-generation relatives. Oral preparations of cephalosporins and penicillins are not recommended for treating pneumonias caused by *P. multocida* due to reduced bioavailability. Fluoroquinolones, including moxifloxacin and levofloxacin, are very active in vitro against *P. multocida* and other *Pasteurella* spp., although published experience in humans is limited. Chloramphenicol, with consideration of its potential toxicities, and tetracycline are effective alternatives when a history of allergic reactions precludes use of a β-lactam agent or fluoroquinolone.

■ *Chlamydia psittaci*

The avian bacterium *Chlamydia psittaci* causes disease in birds and, when transmitted to humans, can cause systemic disease, psittacosis, and pneumonia. Psittacosis is also known as avian chlamydiosis, ornithosis, and "parrot fever." Although psittacine birds (parrots,

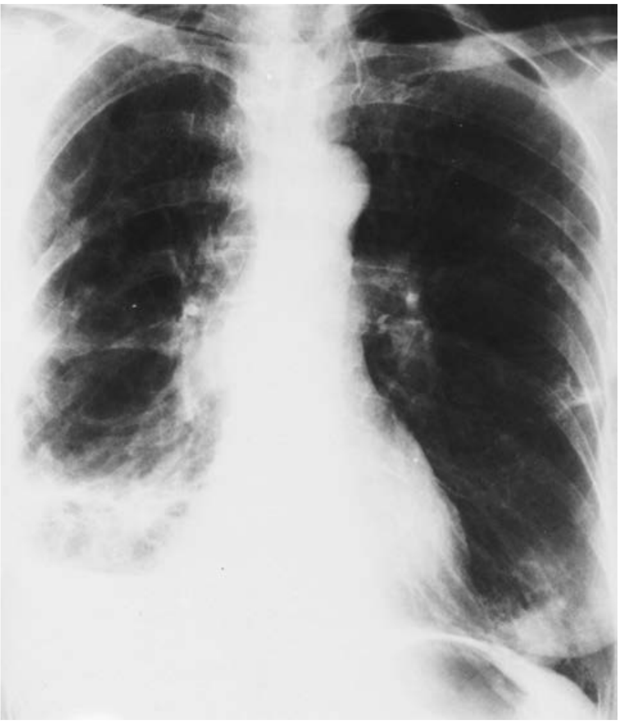

Figure 138-1 Bilateral pneumonia due to *Pasteurella multocida* in a 69-year-old woman suffering from chronic obstructive pulmonary disease and a prior right lower lobectomy for carcinoma. Infiltrates disappeared with penicillin therapy.

cockatiels, macaws, and parakeets) are commonly believed to be the associated risk factor, in fact, most humans contract psittacosis from poultry (especially turkeys) and other non-psittacine birds.

Bacteriology

C. psittaci is an obligate intracellular Gram-negative bacterium. It exists in two forms: elementary bodies and reticulate bodies. The metabolically inactive elementary bodies are ingested by host cells by receptor-mediated endocytosis and then differentiate into metabolically active, but noninfectious, reticulate bodies. The reticulate bodies divide and reorganize into new elementary bodies that then leave the host and can infect new hosts. Since it is an intracellular organism, it does not grow in standard culture medium.

Ecology, Epidemiology, and Pathogenesis

Infection of humans can occur after inhalation of aerosolized avian respiratory secretions, dried feces, or feather dust, and, less commonly, beak-to-mouth contact. Exposure to live poultry or pet birds or habitation in locations with many birds or bird droppings (e.g., under bridges) are epidemiologic clues to the possibility of psittacosis. Human-to-human transmission has not been reported, so isolation of patients is not needed. Outbreaks among poultry workers have occurred.[29] Infection is generally seen in owners of pet birds, pet shop employees, farmers, and workers in zoos, laboratories, and avian quarantine stations. *C. psittaci* infection is a disease reportable to public health departments.

After inhalation the elementary bodies are phagocytized, but they do not fuse with lysosomes and evade destruction, transforming into reticulate bodies and inducing a host response. Inclusion bodies can be seen in alveolar cells on histopathology.

Clinical and Radiologic Features

Symptoms appear 5 to 14 days after infection and include abrupt onset of fever and chills, headache, myalgias, and nonproductive cough. Less common findings include temperature–pulse dissociation, keratoconjunctivitis, and macular rash on the face or extremities. Severe complications include respiratory failure, endocarditis, hepatitis, encephalitis, and sepsis.

Chest radiographs typically reveal lobar infiltrates, commonly in the lower lobes. CT imaging has higher sensitivity and may show nodular infiltrates with surrounding ground-glass opacities.[30]

Diagnosis and Differential Diagnosis

C. psittaci infection can be diagnosed serologically, preferably with a microimmunofluorescent (MIF) antibody test. A titer greater than 1:16 suggests evidence of infection, and demonstration of a fourfold rise is diagnostic for recent infection. Complement fixation assays are available but can cross-react with other *Chlamydia* species. The organism can be cultured, but culture capability is not generally available. Molecular diagnostics of respiratory samples are emerging as a preferred method for diagnosing psittacosis. *C. psittaci* is not included in commercially available "respiratory panel" molecular diagnostic assays. It can be identified in metagenomic "next-generation" assays and at the Centers for Disease Control and Prevention.[29,31] Lower respiratory samples carry a higher yield than nasopharyngeal specimens. In some patients, the organism can also be identified in stool specimens.

The differential diagnosis of pneumonia with fever with no organisms seen on Gram stain of sputum and none isolated on routine culture media includes *Legionella*, *Mycoplasma*, *Chlamydophila pneumoniae*, *Coxiella burnetii*, and viral infections, including the respiratory viruses (SARS, MERS, COVID-19).

Treatment

The preferred treatment for psittacosis is doxycycline, 100 mg twice daily (oral or intravenous) for 7 to 10 days. Azithromycin, 250 to 500 mg once daily for 5 days is adequate alternative treatment for children, pregnant persons, and those who cannot tolerate doxycycline.[32]

■ *Yersinia pestis*

Yersinia pestis, the etiologic agent of the plague, left an indelible mark on humanity long before its late–nineteenth-century isolation and characterization. The organism caused three major pandemics from the sixth through the nineteenth centuries; pulmonary disease in a few victims led to aerosol spread to countless others, resulting in acute primary pneumonia and the "black death" of epidemic plague.

Familial Mediterranean fever has been shown to have mutations that confer heightened resistance to *Y. pestis* that were positively selected in Mediterranean populations.[33] During the period from 1932 through the end of World War II (1945), the Japanese biologic warfare program included use of aerosol drops of *Y. pestis,* as well as infected flea disseminations in occupied China and at the infamous experimental Unit 731. The effectiveness of the flea disseminations remains in question, but the aerosol disposal definitely led to clinical pneumonic plague.

A global scare emanated from India's Maharashtra state in 1994, with reports of suspected pneumonic and bubonic plague; interestingly, some suspected cases were subsequently found to be due to *Burkholderia pseudomallei.*[34] Madagascar accounts for 75% of global plague cases, with an annual incidence of 100 to 700 suspected cases (mainly bubonic plague).[35]

In the United States, fewer than 20 cases of plague are reported yearly, with no human-to-human transmission in the United States since the 1920s. If plague is diagnosed outside an endemic area, bioterrorism should be considered. When *Yersinia* pneumonia occurred in a couple that became ill in New York City, the event was investigated as a potential bioterrorism event until their travel from an endemic area of plague (Santa Fe County, New Mexico) was discovered.[36] Although the bacteria are difficult to process, handle, and disperse in an aerosol form, person-to-person airborne spread is very efficient, and laboratory accidents have occurred.[37]

Ecology, Epidemiology, and Pathogenesis

In the United States, *Y. pestis* is endemic, primarily in the Southwest, in rock squirrels, prairie dogs, rabbits, rats, and other small ground animals. Spread among animals occurs via several species of rodent fleas, especially *Xenopsylla cheopis*. Domestic animals that wander outdoors, like cats, can become infected by direct contact with sick rodents or via rodent flea bites. In addition, cats and dogs can inadvertently carry fleas into the home. Occasionally, rodent die-offs, called epizootics, occur, and many dead animals can be found with viable organisms in carcasses and in the soil surrounding ground dwellings.

Spread to humans occurs when an infected flea feeds on a susceptible person, through handling or ingestion of infected animal tissues, or via inhalation of infectious droplets. Living or working in proximity to local enzootic "hot spots" places certain groups (such as Native Americans, geologists, hikers, veterinarians, and pet owners) at risk. Bubonic and cutaneous plague are usually acquired on exposed areas by contact with infected fleas, but aerosols from ill animals or carcasses can lead to primary pneumonia, pharyngitis, or conjunctivitis. Several cases of cat-to-human aerosol spread have been associated with respiratory infection or submandibular abscesses in pets. Infection control is a concern of clinicians caring for patients with respiratory infection, given the potential for rapid airborne dissemination, especially during coughing and face-to-face contact, resulting in primary pneumonia and the rapid development of adult respiratory distress syndrome (ARDS).

After the organism gains access to human tissues at 37°C, rapid multiplication occurs. The polysaccharide capsule imparts virulence properties that include resisting phagocytosis and persistence of bacteria within nonsensitized monocytes. Virulence factors include a potent endotoxin and V and W antigens of the cell envelope, which influence intracellular survival. A mouse model has demonstrated a biphasic illness with an initial anti-inflammatory phase that rapidly progresses to a highly proinflammatory state by 48 h and death by 3 days. Microarray analysis demonstrates a change in the expression of about 10% of the bacterium's genes after it infects a host.

Clinical and Radiologic Features

Clinical presentations are highly varied and range from subclinical cases (positive serology without evidence of disease) to a chancriform skin lesion (pestis minor abortive bubonic plague), pharyngitis, bubonic plague (with tender, enlarged lymph nodes or "buboes" near the site of a flea bite), septicemic plague (sepsis sometimes complicated by hemorrhage and distal limb necrosis, often the sequelae of untreated bubonic plague), pneumonic plague, and meningitis. The clinical presentation of pneumonia in pneumonic plague depends on the mechanism of spread. In contemporary experience in the United States, cases have been secondary to bubonic plague or primary septicemic plague, rather than from pneumonic plague.[38] The onset of respiratory disease follows days to a week of a febrile illness and is ushered in by the gradual onset of cough, dyspnea, and increasing toxicity. Pink to hemorrhagic frothy sputum, pleurisy, and respiratory distress are additional symptoms. The unique feature in most cases of pneumonia is the epidemiologic association with classic bubonic plague, that is, occurrence in a person in or from an endemic area. From histories of primary inhalation pneumonia described previously, exposure to an index case with pneumonic plague may be followed by rapid development of a fulminating respiratory illness, with dyspnea, cyanosis, and thin, watery sputum that rapidly becomes hemorrhagic. The clinical picture is not unlike that of overwhelming pneumococcal pneumonia, with marked toxicity and mental torpor associated with progressive cyanosis.

The radiologic features of secondary pneumonia include basal segment nodular or hazy airspace infiltrates, hilar and mediastinal node enlargement, and, occasionally, pleural effusions.[39] In primary pneumonia, infiltrates may be minimal during the first 24 h but are followed by progressive airspace disease resembling ARDS or pulmonary edema.

Bacteriology, Diagnosis, and Differential Diagnosis

Y. pestis is a bipolar-staining, Gram-negative bacillus closely related to *Escherichia coli* and other Enterobacteriaceae. Other acute respiratory infections caused by microorganisms that appear as Gram-negative bacilli with bipolar staining must be considered, including *Francisella tularensis* and *P. multocida*. Cultures of blood, sputum, and lymph node aspirates often yield positive results. The organism grows well on blood or MacConkey agar and is identified definitively with differential biochemical tests, agglutination reactions, direct fluorescent antibody staining, and matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry.

Rapid assays for diagnosis of plague have been shown to be useful, such as that based on the antigen F1, which is highly sensitive for diagnosing either pneumonic or bubonic plague and could be useful in detecting plague in remote areas, although false-positive results indicate a need for culture or PCR confirmation; culture is still needed for additional information on antibiotic resistance and bacterial strains.[40] Concerns for laboratory safety have led to routine use of biosafety level 2 (BSL-2) procedures, as well as better communication between clinicians and microbiology laboratory personnel in suspected cases.[37] Postinfection confirmatory serologic studies can be done using passive hemagglutination testing on acute and convalescent sera at selected reference laboratories, such as the U.S. Centers for Diseases Control and Prevention (CDC).

The differential diagnosis for pneumonic plague includes infectious agents that cause community acquired pneumonia, such as pneumococcus, *Streptococcus*, *H. influenzae*, viruses, and unusual etiologies like anthrax or tularemia.

Treatment and Prevention

A review of published cases of treated plague from 1937 to 2019 found an overall case fatality rate of 20%.[41] Combination treatment with either streptomycin or gentamicin and doxycycline or tetracycline has been the treatment of choice for serious plague infections;[42] some experts recommend starting doxycycline whenever the disease is suspected.[43] Fluoroquinolones, such as ciprofloxacin, and chloramphenicol also are effective in treating pneumonia.[41,42] Multidrug-resistant plague has been reported, and clinicians should be aware of local trends, as well as the potential for terrorist-instigated modifications in antibiotic susceptibility.

Persons suspected of having plague pneumonia should be rapidly isolated and strict contact, respiratory, and conjunctival precautions instituted. Anyone exposed face-to-face with a coughing patient, including health care workers, should be given preventive doxycycline or ciprofloxacin (trimethoprim-sulfamethoxazole in pregnant women and children). Isolation procedures are continued until the productive cough resolves or sputum cultures are negative for *Y. pestis*.

An inactivated vaccine is available for laboratory workers and others with frequent exposure to the microorganisms or hyperendemic areas, although it is not commercially available in most countries and does not appear to protect against pneumonic plague.[44] Careful surveillance of ground rodent populations, posting warnings in endemic regions, watching for die-offs that indicate epizootic spread, and spraying for local flea control may also be effective preventive measures, along with public education.[38]

Francisella tularensis

Tularemia is a common animal disease in the United States as well as many other regions of the temperate globe. The causative agent, *F. tularensis*, is ubiquitous, distributed among many species of wild and domestic animals and birds. As with plague, the major clinical manifestations include skin lesions and swollen or draining regional lymph nodes. In addition to primary inhalation pneumonia, pulmonary invasion is seen following bacteremia in 10% to 15% of ulceroglandular cases and in more than 50% of patients with the typhoidal syndrome. Some 200 to 300 human cases are reported in the United States yearly, but this is probably an underestimate; approximately 50% of all tularemia cases each year in the United States occur in Arkansas, Kansas, Oklahoma, and Missouri.[45] In the summer of 2000, an outbreak of pneumonic tularemia occurred on Martha's Vineyard, Massachusetts, and 11 of 15 patients were diagnosed with primary pneumonic tularemia; lawn mowing and brush cutting were found to be risk factors for infection.[46] An epidemic of tularemic pharyngitis from ingestion of contaminated well water and food occurred in war-torn Western Kosovo primarily among young children originally suspected of having group A streptococcal pharyngitis, with no secondary pneumonias reported.[47]

Bacteriology

F. tularensis is a fragile-appearing Gram-negative coccobacillary organism that is quite fastidious and grows poorly on artificial media unless fortified with serum and cysteine (or sulfhydryl compounds). The potential for laboratory-acquired inhalation or ingestion-associated disease is great. Most routine laboratories do not attempt to culture the organism, leaving this to special reference centers. Identification is based on morphologic and biochemical determinants, but direct fluorescent staining or agglutination reactions with specific antisera also are useful.

Ecology, Epidemiology, and Pathogenesis

The organism is associated with more than 100 species of wild and domestic animals and birds, including aquatic mammals, but most clinical cases arise from contact with rabbits, squirrels, or arthropods. Of great concern is the recent fad for exotic pets; tularemia in prairie dogs has led to spread in holding pens and to human transmission. In cold weather the organism can persist in water and mud environments for weeks to months.

Fewer than half of human cases are acquired from contact with infected animals during hunting, trapping, and other outdoor pursuits, especially during colder months. In southern areas, or in the summer season in northern latitudes, gardening and lawn mowing without animal contact are becoming important methods of dissemination from disturbed soil. Bloodsucking arthropods constitute a significant and increasing mode of spread, especially in warmer seasons. Ingestion of contaminated food or water,[47] animal bites, conjunctival contact, and aerosol dissemination also are important mechanisms for acquiring the pathogen. In recent years, cases secondary to arthropods have been more frequent than those associated with direct animal contact, although domestic cat bites[48] and airborne spread appear to be increasing. Human-to-human transmission is rare, in contrast to the significant theoretical potential for spread of pneumonic plague. *F. tularensis* is a category A bioterrorism agent because of potential for aerosol release.[49] Aerosol release could lead to respiratory, as well as cutaneous, conjunctival, or pharyngeal disease.

F. tularensis contains a number of protein and polysaccharide antigens in the cell envelope, as well as an endotoxin component that is similar to endotoxins of other Gram-negative microorganisms. The organism is capable of remaining viable in reticuloendothelial cells of nonimmune subjects and in macrophages that have not been activated by recent exposure to other intracellular pathogens. As few as 10 to 50 organisms can initiate disease following cutaneous penetration or by inhalation, but a significant number are required when the challenge is through ingestion of contaminated water or foods. Local growth usually is followed by regional node suppuration and, occasionally, bacteremic dissemination to many organs, including the lungs. Primary pneumonia follows inhalation of organisms, resulting in numerous areas of inflammation, necrosis, a tendency to granuloma formation, hilar and mediastinal adenopathy, and pleural inflammation and effusion.

Clinical and Radiologic Features

Respiratory disease is heralded by the onset of a nonproductive cough, usually in a febrile patient ill with the ulceroglandular form of tularemia.[50] In the absence of a local chancriform lesion or a tender swollen lymph node (bubo), the disease may be dominated by constitutional symptoms, with high fever, severe headache, prominent myalgias, and shaking chills (typhoidal tularemia). Pneumonia following an inhalation exposure results in cough, dyspnea, and, occasionally, pleurisy. Respiratory disease can be subtle, and the diagnosis may be apparent only if a chest radiograph is done. Pleural effusions may be serosanguineous or frankly bloody, an uncommon finding with other pulmonary infections except anthrax.

Radiologic changes include evidence of parenchymal and pleural disease, which is often out of proportion to the findings on examination. Diffuse areas of bronchopneumonia occur, with hilar node enlargement and occasionally mediastinal widening, similar to the radiologic appearance of anthrax. Unilateral or bilateral pleural effusions are often noted (Fig. 138-2).

Diagnosis and Differential Diagnosis

Any febrile patient with animal, arthropod, or landscaping exposure in an endemic region, especially one presenting with a chancriform skin lesion and/or a tender lymph node, should be evaluated for tularemia. Cough, when present, is usually nonproductive, and blood cultures are seldom positive. Characteristic organisms are rarely seen in pleural fluid or aspirates of suppurating nodes. Direct fluorescent antibody staining of exudates can confirm the diagnosis, but this method is not widely available. Serologic testing remains the method of choice for confirming a diagnosis. ELISA and microagglutination methods may be more sensitive than tube agglutination testing. A single convalescent titer of 1:160 or greater is considered highly suspect for active disease, but a fourfold rise in titer between acute and convalescent (1–5 weeks) sera is more reliable since antibodies can persist for many years after infection. Polymerase chain reaction and other molecular biologic techniques have successfully diagnosed tularemia in human specimens. An elevated blood level of creatine phosphokinase may be a clue that tularemia-induced rhabdomyolysis is a response to the acute infection, especially in highly endemic areas.

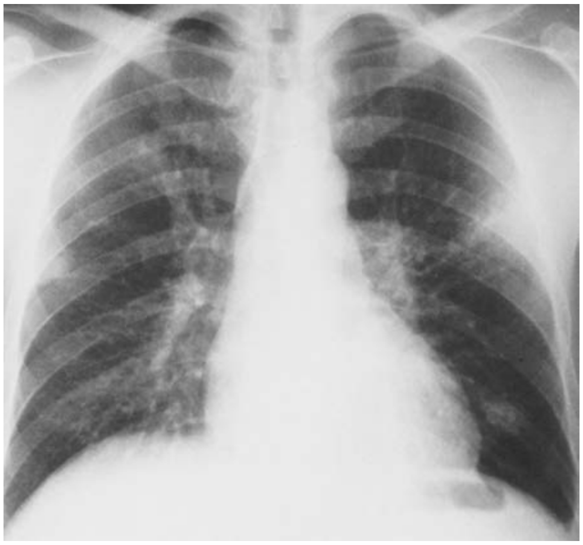

Figure 138-2 Patchy nodular and bronchopneumonia, hilar adenopathy, and left pleural effusion due to *Francisella tularensis* in a 38-year-old veterinarian exposed to a cat dying with a respiratory infection. All the findings resolved with tetracycline therapy.

F. tularensis can be cultured from blood, sputum, and other body tissues. If tularemia is suspected, it is important to notify the microbiology laboratory staff because of the high risk of aerosolizing the organism if the culture plate is opened outside of a biosafety containment hood.

Perplexing diseases that are also associated with outdoor and animal exposures, such as psittacosis and Q fever, may be confused with tularemia. Legionnaires' disease and *Mycoplasma* pneumonia can present with similar clinical courses, without diagnostic sputum. Plague, tuberculosis, and systemic fungal infections produce a spectrum of acute to chronic respiratory manifestations that can mimic pulmonary tularemia.

Treatment and Prevention

Streptomycin was the first effective antibiotic for treating all forms of tularemia, but it is not readily available.[50] Gentamicin appears to be equally potent and has the advantage of a broader spectrum of activity if one is initiating treatment when the etiologic diagnosis is less secure.[50] Additionally, it can be given intravenously, and blood levels can be monitored. Tobramycin, however, appears to be unreliable and, therefore, should not be substituted for other aminoglycosides. Recent experience confirms that results of therapy are optimal when an aminoglycoside is chosen early in the clinical illness. Tetracycline/doxycycline, ciprofloxacin, and chloramphenicol may be useful alternatives when an aminoglycoside is contraindicated. Relapse rates are higher with the bacteriostatic combination of tetracycline/doxycycline and chloramphenicol, especially when given for less than 2 weeks. β-Lactam antibiotics are not effective. The prognosis is excellent with appropriate antimicrobial therapy.

Cautious practices are required when one is dealing with animals and their carcasses. Using gloves, cooking wild animal meat thoroughly, and wearing protective clothing and repellants to avoid blood-sucking arthropods are helpful measures. An attenuated live vaccine strain (LVS) has been developed but is not commercially available. With the increase in concern in bioterrorism, the Tularemia Vaccine Study Group and others are working to develop an improved vaccine.[51]

■ *Rhodococcus equi*

Rhodococcus equi, formerly known as *Corynebacterium equi*, was first isolated in 1923 by Magnussen when it was identified as a cause of suppurative pneumonia in foals. It was later shown to be a frequent pathogen in horses, cattle, and swine. First described as a pathogen in humans in 1967, the majority of recognized cases in recent years have been in immunocompromised patients, especially individuals receiving corticosteroids, those infected with the human immunodeficiency virus,[52] or those who have undergone solid organ transplantation.[53,54] Pneumonia with the related bacteria *Rhodococcus defluvii* has been reported in a patient with AIDS.[55]

Bacteriology, Ecology, Epidemiology, and Pathogenesis

Rhodococcus is a pleomorphic Gram-positive bacillus in the order Actinomycetales. It grows well aerobically on most media, at 37°C, as mucoid pale-pink or salmon-pink colonies that are usually observed by 48 h of incubation. *R. equi* has a high cell wall mycolic acid content and is acid-fast, similar to *Nocardia* spp. and Mycobacteriaceae. Some strains ferment glucose, but the majority will not ferment carbohydrates. Most produce catalase and hydrogen sulfide. β-Lactamase is present in some strains.

Most reported cases occurring in humans without HIV infection have been in patients who had significant contact either with livestock or soil and environments that were heavily contaminated with livestock waste. In contrast, HIV-related *Rhodococcus* disease appears to occur in patients who do not have any particular environmental exposure history—implying a wider distribution of the organism.[52] There is no known geographic endemicity.

R. equi usually is inhaled, although soft-tissue infections after cutaneous inoculation can occur. As an intracellular pathogen it causes disease primarily in patients with impaired cell-mediated immunity and defects in phagocytic processing of organisms. Diseased tissues usually show a necrotizing granulomatous reaction, with histiocytes and macrophages frequently containing bacteria. In contrast to lesions associated with *Mycobacterium tuberculosis* and systemic fungi, there is also a prominent infiltration of neutrophils in the affected areas, a characteristic shared with other *Actinomyces* spp.

Clinical and Radiologic Features

Patients frequently complain of indolent symptoms, such as fever, nonproductive cough, and mild dyspnea.[53] Typically there is a paucity of findings on physical examination of the chest, but signs of consolidation and pleural friction rubs may be present. Patients with HIV infection generally present in a manner similar to patients without HIV infection, although pleuritic chest pain may be more common. In HIV-infected patients, *R. equi* disease tends to occur after there has been significant deterioration in their immune systems, with CD4 lymphocyte counts less than 200 cells/mm^3.[52] It is often found associated with other pulmonary infections. Extrapulmonary dissemination occurs in HIV-infected and non–HIV-infected patients, but there appears to be a significantly greater rate of recovery of the organism from blood cultures in HIV patients. The central nervous system is a recognized site of metastatic infection, as it is for *Nocardia* spp. The immune reconstitution inflammatory syndrome (IRIS) has been reported in patients with HIV after starting antiretroviral therapy.[56,57] *R. equi* has been reported as an opportunistic pathogen in patients with solid organ transplants.[58,59]

The most common radiographic abnormalities are lobar infiltrates, which usually evolve into nodular or cavitating lesions within weeks or months. There is no predilection for involvement of any particular lobe. Pleural effusions are common, occurring in up to 40% of HIV patients with pulmonary *R. equi* infection. Significant hilar adenopathy is unusual.

Diagnosis and Differential Diagnosis

R. equi can readily be cultured from sputum, bronchial lavage, pleural fluid, or other infected tissue and often from blood. Since the organisms stain as pleomorphic Gram-positive bacilli, grow readily on most media, and are usually catalase producers, they can be mistaken for "diphtheroid" or "Coryneform" contaminants unless further testing is done; therefore it is important for the clinician to alert the microbiology laboratory staff if the possibility of *R. equi* is entertained. *R. equi is* slightly acid-fast with modified Ziehl-Neelsen stain.

Rhodococci share many microbiologic features with mycobacteria and *Nocardia*, and this may account for similarities in the subacute to chronic evolution of the disease. The high mycolic acid content of their cell walls results in their acid-fast staining properties and may also play a role in their similar clinical and pathologic manifestations. *Nocardia* spp., *M. tuberculosis*, and nontuberculous mycobacteria also should be considered when acid-fast organisms are found in clinical specimens, especially in immunocompromised patients with nodular or cavitary pneumonia (Table 138-2).

Other considerations in the differential diagnosis of nodular or cavitating pulmonary lesions include malignancy, fungal infection such as *Cryptococcus neoformans*, anaerobic lung abscess, and necrotizing pneumonia caused by facultative bacteria such as *Staphylococcus aureus* or *Klebsiella pneumoniae*.

Treatment and Prevention

Antibiotic therapy alone is usually adequate to achieve cure.[53] As with mycobacterial infections, multidrug regimens and therapy of 2 to 6 months' duration may be needed, especially in immunocompromised patients. Because *R. equi* is an intracellular pathogen that multiplies in phagocytes, antibiotics capable of achieving

TABLE 138-2 Diagnosing *Rhodococcus equi* Respiratory Infection

History of exposure to horses, cattle, or their environment
Immunocompromised host: malignancy, steroids, HIV
Cavitary or nodular infiltrates on radiograph
Gram-positive pleomorphic bacilli
Modified acid fast
Pale-pink or salmon-pink mucoid colonies
Grows rapidly, aerobically on most media
Differential diagnosis includes *Nocardia* species, mycobacteria

high intracellular levels, such as rifampin or fluoroquinolones and macrolides, are preferred. Chloramphenicol, sulfonamides, and aminoglycosides are active against most isolates. In some patients, surgical resection of a nodular or cavitating lesion may be necessary to achieve cure. For prevention, we advise immunocompromised hosts to avoid contact with horses and their environments.

ENVIRONMENTAL AND ANIMAL PRODUCT PNEUMONIAS

This section focuses on diseases that are spread to humans predominantly from contact with contaminated soil, water, foods, or animal structural elements. The diagnosis usually depends on a careful history focused on epidemiologic and ecologic characteristics. Once alerted, the clinician can request studies that may reveal the cause of these often obscure diseases. It should be apparent that this distinction—an association with environmental contamination and animal products—can be somewhat arbitrary. For example, anthrax bacilli can spread directly from animals to humans, and *R. equi* contamination of soil could place it in this group, rather than in the group infected via direct animal exposure.

■ *Bacillus anthracis* (Anthrax)

Inhalation anthrax was a common enough disease in the nineteenth and early twentieth centuries to be referred to variously as Bradford's disease, after the English town, and woolsorter's disease for the epidemiologic association with the sheep industry. Fortunately, inhalation anthrax has become a rare spontaneously acquired disease, accounting for less than 5% of anthrax cases (95% are cutaneous, and gastrointestinal disease is very rare).[60] An epidemic of anthrax in 1979, following an accidental release at a bioweapons facility occurred in the area of Sverdlovsk (now renamed Ekaterinburg) in the former USSR, resulted in 42 deaths due to inhalational anthrax.[61] In 2001 there were 18 confirmed cases of inhalational and cutaneous anthrax and an additional 4 suspected cases of cutaneous anthrax in the United States; of the 22 cases, at least 20 were definitively related to mail contaminated with the same strain of *B. anthracis*. The potential zoonotic as well as terrorist-induced exposure of susceptible persons to *Bacillus anthracis* spores argues for including this devastating, often lethal, disease in this chapter.

Bacteriology, Ecology, Epidemiology, and Pathogenesis

B. anthracis is a large (red blood cell diameter), square-ended bacillus that stains Gram-positive and tends to form chains. Growth on sheep blood agar results in dull, sticky, irregularly shaped colonies within 24 h. The organism possesses a polyglutamic acid capsule, produces a complex potent trivalent exotoxin, and, under adverse conditions, forms highly refractile, centrally located spores that are very resistant to temperature and moisture extremes.

Anthrax is primarily a disease of herbivores. The resistant spores are present after animals dying of the disease contaminate the soil. Anthrax "hot spots" are found internationally, and in milder regions in the United States, such as Oklahoma, Texas, and California. Optimal conditions for germination of spores and multiplication of bacilli include alkaline soils containing adequate calcium and low areas that are wet for prolonged periods, termed incubator areas, with thick vegetation that produces heat with decay. Periods of extreme drought after a rainy season favor spore formation. Climate change has increased rates of anthrax in new regions. Animals grazing in these areas inhale, ingest, or pick up spores on their fur. The cycle is completed when an animal develops the disease, dies, and returns organisms to the soil for eventual sporulation.

Inhalation anthrax rarely occurs from contact with live infected animals, and there is no human-to-human transmission. The animal hide industry, exposure to bone meal fertilizer,[62] and use of imported goat skins and raw wool in home crafts can lead to inhalation of spores and clinical disease in susceptible persons.[63] Inhalation of spores from wind-disturbed soil can also cause infection.

Inhalation results in activation of bronchial clearing mechanisms and entrapment of spores in hilar and mediastinal nodes, where reversion to vegetative bacilli can occur. The polyglutamic acid capsule is antiphagocytic, and the extracellular microorganisms produce a trivalent protein exotoxin that leads acutely to profound local edema, accompanied by hemorrhage in the mediastinal and hilar areas, with compromise of airflow. The pathogenesis of this tripartite toxin consists of a protective antigen, an edema factor, and a lethal factor.

The protective antigen fragment of the toxin serves as the binding domain, essential for cell penetration by both the edema factor and the lethal portions of the molecule.

Edema factor is a potent adenylate cyclase; activation within mammalian cells stimulates production of cAMP, and the resultant flux of sodium, potassium, and water leads to abundant local edema. When this process takes place in hilar and mediastinal nodes and surrounding tissues, profound airway obstruction ensues, with pooling of secretions and if the patient survives, secondary bacterial pneumonia.

Lethal factor is a potent protease that acts primarily in macrophages, activating intracellular mitogen-activated protein kinase, leading to production of proinflammatory cytokines and reactive oxygen intermediates. The pathogen rarely invades lung tissue, as death from asphyxia occurs rapidly, usually associated with pleural effusions (secondary to lymphatic obstruction) and hemorrhagic septicemic lesions in many organs. In a large inoculum exposure, as occurred in the 2001 "mail room" criminal outbreak, patients can develop disease within the pulmonary parenchyma and the gastrointestinal tract.[60]

Clinical and Radiologic Features

In spontaneously occurring disease, the onset is insidious, usually resembling a nonspecific febrile influenza–like illness.[20,60] Malaise and muscle aches, low-grade fever, mild headache, coryza, mild and nonproductive cough, pharyngitis, and chest pains have been described as early symptoms. At this stage, it is hardly possible for the physician to entertain a presumptive or possible diagnosis of anthrax unless a history of industrial or craft-related exposure to imported animal hair or hides or to animal products, such as bone meal, is obtained. Watery nasal discharge can be indicative of nasal or paranasal sinus involvement. Cough may represent hilar and mediastinal node swelling, and careful auscultation may reveal prolonged expiratory wheezes or evidence of a pleural effusion. Chest pain may be the first clue that hilar and mediastinal inflammation is present.

Within hours to a few days, the mild complaints abruptly worsen, and acute airway obstructive features dominate the clinical picture. Any activity precipitates severe dyspnea, stridor, and wheezing. Impairment of the nervous system (hemorrhagic meningitis) and hypoxemia result in decreasing levels of consciousness. Edema of the pharynx, neck, and anterior chest may develop. Chest pain, fever, and cyanosis are progressive. Worsening airway obstruction can lead to intercostal space retraction, and pleural effusions are noted on examination. Death usually occurs within hours to a day once acute respiratory symptoms are present. In the 2001 exposures to significant spore burden, some patients had a biphasic illness with early upper respiratory and gastrointestinal symptoms, followed by respiratory distress days later.[60]

Inhalation anthrax is primarily a mediastinitis, and the radiologic features mostly reflect the pathologic findings.[64] Widening of the mediastinum or prominence of hilar nodes is the earliest radiologic finding, sometimes accompanied by pleural effusion; in advanced cases, the mediastinal width may be greater than 9 cm and sharply demarcated from surrounding lung tissue given the absence of airspace consolidation. There may be perihilar and peribronchial streaking from edema and hemorrhage.

Diagnosis and Differential Diagnosis

A physician alerted to the possibility of inhalation anthrax has few laboratory studies to rely on. Nasal secretions and sputum rarely reveal the characteristic bulky Gram-positive bacilli. Half of the reported cases of inhalation disease are complicated by meningitis, and hemorrhagic cerebrospinal fluid with observable organisms can confirm the diagnosis. There are no available data on examination of buffy-coat smears, and therapy must be instituted before blood culture results become available. Microscopic examination of pleural fluid may reveal the characteristic organisms. The most commonly recognized form of anthrax, the cutaneous chancriform necrotic lesion, does not usually accompany inhalation cases in naturally occurring disease.

Differential diagnosis includes other causes of acute mediastinitis, such as esophageal perforation. Tuberculosis, histoplasmosis, and tularemia rarely produce acute respiratory failure as part of hilar and mediastinal node involvement. Hantavirus pulmonary syndrome is associated with similar central pulmonary changes, including edema but should be separable from anthrax by epidemiologic data, the presence of air space disease, and absence of mediastinal involvement. Lymphoproliferative diseases that may have mediastinal involvement, like nodular sclerosing Hodgkin disease, evolve at a slower pace. Chest wall and neck edema, associated with acute breathing difficulties, can accompany diphtheria or *Streptococcus pyogenes* pneumonia, with bilateral pleural effusions, an early manifestation of streptococcal pneumonia. Acute epiglottitis caused by *Haemophilus influenzae* can mimic some manifestations of inhalation anthrax.

Treatment and Prevention

Combination therapy is currently recommended based upon the "mail room" epidemic of 2001.[20] Regimens with ciprofloxacin or doxycycline, plus clindamycin (to block toxin production) and rifampin (which penetrates CSF and intracellular sites) are favored. Monotherapy with penicillin should not be used in inhalation disease since multiple strains, including the 2001 "mail room" outbreak, produce an inducible β-lactamase. Treatment is recommended for 60 days to avoid activation of persistent spore forms.[20] Corticosteroids should be considered for treatment of significant mediastinal edema or meningitis. Early thoracentesis appears to be beneficial. Unfortunately, the airway obstructive manifestations are not reversible once acute respiratory manifestations have progressed. Assisted ventilation and use of diuretics are all reasonable support efforts, but they are generally not successful due to the continued effects of tissue-bound toxin. Before 2001, mortality in inhalation anthrax approached 100%. In the 2001 experience, mortality was 45% (5 of 13 respiratory cases); knowledge gained from that experience might prove helpful in future cases.[60]

In the animal hide industry, vaccination is the cornerstone of preventing anthrax. Plant workers and others in contact with potentially infected animal products should be immunized with the currently available vaccine: anthrax vaccine adsorbed.[65] Numerous new vaccines are under development, many based upon the protective antigen segment of the toxin. Animal products imported from endemic regions of the world (e.g., Africa, the Near East, the Indian subcontinent) are steam sterilized, and there is modern ventilation in the workplace. At-risk persons are those who are unlikely to be vaccinated, that is, those who service these plants, such as ventilation specialists and other transients. Bone meal should be treated by heat sterilization before packaging for use by commercial and home gardeners.[62] Those who import yarn from endemic areas are at special risk unless the rules for commercial hide sterilization are also imposed on casual animal hair imports.[63] A recent case of inhalation anthrax in a drum maker who carried goatskins into the United States emphasizes the need for appropriate education and importation controls.[63,66]

■ *Brucella* Species

Lung involvement is an uncommon presentation of brucellosis, yet respiratory symptoms can be prominent manifestations of the disease.[67,68] Brucellosis is often a prolonged and perplexing illness however, and in chronic cases pleurisy, hilar adenopathy, and nodular lung lesions can be encountered.[69] Exposure to animals, animal-based foods (cheeses or meats), or residence in an endemic region is usually found.

Bacteriology, Ecology, Epidemiology, and Pathogenesis

Brucellae are slow growing, small, coccobacillary, Gram-negative, nonmotile, aerobic, nonencapsulated organisms that are now classified with the Alphaproteobacteria, closely related to *Rochalimaea* and *Bartonella* spp. Carbon dioxide is essential for growth of *Brucella abortus*, and all four pathogenic species require growth medium enriched with vitamins and serum. With the aid of a battery of biochemical, metabolic, and immunologic criteria, Brucellae pathogenic for humans can be classified as *B. abortus*, *B. suis*, *B. melitensis*, and *B. canis*. In general, the species designation corresponds to the animal usually colonized or diseased.

Brucellae spp. are distributed worldwide. Infection and disease occur primarily in domestic animals in geographic regions such as the Mediterranean (*B. melitensis*), worldwide except in areas of Europe and Japan (*B. abortus*), the midwestern United States (*B. suis*), and North and Latin America (*B. canis*). Spread from one region to another occurs with live animal movements or when infected animal products are commercially or privately shipped.

The epidemiology of brucellosis is intimately related to the association of susceptible persons with infected animals and animal products. Abattoir workers (especially slaughterers) and others in the meat-processing industry, farmers, dairy workers, veterinarians, and bacteriology laboratory technicians account for most cases in the United States, with a general preponderance of male patients. Human brucellosis is rare in the United States, with 80 to 120 cases reported annually; most of these are associated with *Brucella* exposures abroad.[70] Worldwide approximately 500,000 cases are reported annually.[71] Also at risk are military personnel and travelers to endemic regions who eat local foods and persons who consume imported goat cheese, sausage, and other unpasteurized edibles from endemic areas. The organisms are usually acquired by ingestion, through skin abrasions and lacerations, or via conjunctival inoculation. Aerosol spread can be a route in abattoir workers;[72,73] inhalation of only 10 to 100 bacteria can cause disease in humans.[74] No human-to-human transmission has been reported.

Organisms invade the local reticuloendothelial system and lymph nodes, followed by bacteremic spread to many organs during the following weeks. There is increasing evidence that the aerosol route may be a rare but especially efficient portal of entry. The distribution of nodular lesions in lung tissue is primarily in basal segments, however, which argues for bacteremia rather than primarily an inhalation mechanism for most cases of pulmonary disease.

A race between bacterial growth and the development of cell-mediated immunity ensues, primarily in lymph nodes and the reticuloendothelial system. As with tuberculosis, the result is often containment within granulomas that eventually become fibrotic or calcify. Species and strain differences account for the wide variety of tissue reactions encountered, including granulomas, necrosis, and abscess formation. Smooth variants appear to be more virulent than rough forms, and many contain polysaccharide polymers in their superficial envelope that, like true capsules, inhibit phagocytosis and intracellular destruction. Lipopolysaccharide endotoxin is present in the cell envelope and may be responsible for profound metabolic and cardiovascular effects as organisms are killed during therapy, releasing endotoxin. *Brucella* spp. can survive within nonstimulated macrophages while escaping host antibodies and antibiotic therapy. As macrophages become activated, they develop the capacity to rapidly kill *Brucella* organisms. Host immunity appears to be primarily cell mediated. Impairment of cell-mediated immunity can lead to reactivation of latent *Brucella* or greater susceptibility and severity with primary infection.

Clinical and Radiologic Features

Clinical brucellosis is dominated by nonspecific flu-like constitutional manifestations, including fever and headache. Nonproductive cough has been described in 10% to 33% of cases, but other indicators of respiratory involvement are rarely or poorly described. In one review of 59 cases, dyspnea and pleuritic chest pain were present in 10% of the patients. Hoarseness, bronchitis, and, rarely, mucopurulent, purulent, or hemorrhagic sputum have been noted. Only one patient with verified pulmonary invasion was described in a review of 160 acute and subacute cases of brucellosis reported in 1974. In a recent description of 37 patients with *Brucella* respiratory disease, 32% had typical lobar pneumonia, 41% had an interstitial pattern on chest x-ray, and a honeycomb pattern was seen in 11%, with pleural effusion(s) in the same number.[75] Extrapulmonary disease was found in 76% of patients, with 22% having greater than one extrapulmonary complication. Unilateral hilar adenopathy and granulomas occur occasionally.

Diagnosis and Differential Diagnosis

During the acute illness or in relapse, blood cultures may be positive. In the presence of an infiltrate or pleural effusion, material for Gram stain and culture should be obtained, although the yield is small. A positive culture may be obtained from a lymph node or pulmonary granuloma biopsy. In most cases the diagnosis is made from a fourfold rise or a single value of at least 1:160 in the agglutination titer. Occasionally “inhibitory” or blocking antibodies are present in the serum, and a positive titer is discovered only if the serum is further diluted (so-called prozone phenomenon). The standard tube agglutination test utilizes *B. abortus* as the antigen and detects antibodies to *B. suis* and *B. melitensis*, but not to *B. canis*. Direct comparison of the clinical manifestations of *B. abortus* with *B. melitensis* reveals that the latter presents more acutely as fevers of unknown origin with statistically significant higher rates of abdominal tenderness, hepatomegaly, splenomegaly, thrombocytopenia, pancytopenia, and hepatic dysfunction. Acute disease can be confused with miliary tuberculosis, endocarditis, tularemia, disseminated histoplasmosis, and lymphoproliferative diseases. Subacute and chronic cases must be differentiated from subacute bacterial endocarditis, tuberculosis, histoplasmosis, other systemic fungal infections, and sarcoidosis.

Treatment and Prevention

The combination of doxycycline with rifampin for 4 to 6 weeks is one of the most effective and easiest oral antibiotic regimens.[67,76] Doxycycline combined with streptomycin or gentamicin, or trimethoprim-sulfamethoxazole also are effective alternative regimens. Fluoroquinolones are active in vitro, but they are associated with an unacceptably high relapse rate as monotherapy.

Rigorous control measures, such as herd inspections and vaccination procedures, have dramatically reduced enzootic and epizootic disease in many regions. Quarantine and inspection activities have diminished the risk of importing infected animals into the United States. The program for *B. suis* eradication has been ineffective, and human cases of *B. suis* now outnumber those due to *B. abortus*. Education programs for workers in abattoirs have been aimed at protecting and preventing skin lacerations and eye contamination.

■ *Burkholderia (Pseudomonas) pseudomallei*

Melioidosis ranges from an acute necrotizing to a chronic fibronodular cavitating process indistinguishable from tuberculosis.[77] It is a disease of tropical latitudes and is associated with rural settings.[78] Most cases are in the heavily endemic regions of Southeast Asia, including northeast Thailand, Malaysia, and Singapore, as well as northern Australia. A number of cases were noted in survivors of the 2004 tsunami[78] and after flooding in Puerto Rico.[79]

Sporadic cases have been reported among residents of or travelers to central and South America, and clusters have been reported in northeastern Brazil. Infection with *Burkholderia pseudomallei* has been seen in the United States almost exclusively after a latent period of months to years in military personnel returning from regions such as Vietnam and in refugees from endemic areas, and there are similar case reports from areas such as the Caribbean,[79] Africa, the Middle East, and Brazil. The mortality rate can reach 40%.[77] Cases have also been reported in nontravelers in the United States, possibly linked to imported products since the organism was not isolated from environmental sources.[80]

Bacteriology, Ecology, Epidemiology, and Pathogenesis

The organism is an aerobic, bipolar-staining, Gram-negative bacillus that is motile and lacks a well-defined capsule. Similar to *Pseudomonas*, *B. pseudomallei* grows well on minimal as well as enriched media, including blood and MacConkey agar used in most routine laboratories. Typical colonies are distinctive in appearance, rough or wrinkled, and cream to orange in color; they may resemble a flower with folds radiating from a central core. Colonies have the typical musty, fruity odor of the pseudomonads but lack pyocyanin and other pigments that characteristically color the surrounding medium. Identification rests on a battery of biochemical reactions, and confirmation is based on agglutination or fluorescent antibody studies.

B. pseudomallei occupies an environmental niche that includes moist soils, rice paddies, and other stagnant water in tropical and subtropical regions, approximately subtended by latitude 20 degrees north to 20 degrees south. Evidence of subclinical and clinical disease occurs in wild and domestic animal populations, as well as in humans living permanently or transiently in rural endemic areas, especially in southeast Asia and northeast Australia. As many as 10% to 30% of native populations have evidence of prior infection based on serologic data. Approximately 1% to 2% of healthy American military personnel who served in Southeast Asia have antibodies, and almost 9% of soldiers wounded in Vietnam have titers for *B. pseudomallei*. A significant number of the approximately 3 million U.S. soldiers who fought in the region constitute a reservoir of latent disease that, like tuberculosis, can become active even decades later, far removed from an endemic area. Refugees from Southeast Asia represent another important group of potential carriers.

Transmission is mainly by direct contact with contaminated soil or water through minor abrasions or major wounds. Ingestion and inhalation are probably less frequent modes of spread, but common source outbreaks occur in animals and humans. Animal-to-human disease is very rare, with only three cases reported from Australia. Human-to-human spread also has been exceptional, associated with breastfeeding or urinary catheter contamination, or occurring between siblings with cystic fibrosis. In endemic regions, lack of previous exposure and debilitating circumstances, including malnutrition and uncontrolled diabetes, may increase susceptibility to infection and disease. In a survey of 524 patients with melioidosis in northeast Thailand, coinfection with HIV was detected in only 8 of 524 adults (1.5%); clinical presentation and acute outcome were similar in HIV-positive and -negative patients. Although it is not clear if solid organ transplant alters the risk for melioidosis, pleuropulmonary melioidosis with septicemia has been reported in a renal transplant patient in Australia; although she was not from an endemic region, on revisiting her travel history, it was found that the patient had travelled to the endemic tropical northern Queensland part of Australia during the rainy season.[81]

Pathogenesis and Pathophysiology

The presence of potent endotoxin and the absence of an antiphagocytic capsule have been noted. Acute infections are associated with necrotic lesions containing polymorphonuclear neutrophils (PMNs) in lung and other tissues. Chronic infections, especially in the respiratory tract, resemble tuberculosis with granuloma formation, Langhans or foreign-body giant cells, central caseating necrosis, and occasionally a PMN response in the necrotic area. Activation of latent infection after a period of months or even decades occurs. This “awakening” can be in the wake of influenza and other acute infections, acute stress (trauma, thermal burn, surgery, etc.), and immunosuppressing illnesses or therapies, but spontaneous activation also occurs. The location of dormant microorganisms and the specific molecular events that stimulate recurrent disease are unknown but remain an area of active investigation.

An antecedent local infection in an area of broken skin can be followed by acute septicemia in nonimmune subjects. Initial pulmonary lesions occur predominantly in the better-vascularized basal segments, consistent with bacteremic spread to the lungs. Eventually, other areas of the lungs and other tissues are affected. Subacute and chronic disease may result from a subclinical primary focus, often localized in an apical segment, resembling tuberculosis in location and propensity for granuloma formation and cavitation. Subpleural invasion can result in empyema or sympathetic sterile effusions.

Clinical and Radiologic Features

Primary melioidosis occurs within a few days to 3 weeks of exposure, usually via a cutaneous wound in persons from (or with recent exposure to) an endemic area. The portal of entry may be present as a small necrotic skin lesion in an area of known trauma, with accompanying cellulitis or lymphangitis. Although the acute phase of melioidosis is the most common manifestation in endemic areas, it is very rarely seen in the United States. In addition to marked toxicity and high fevers, respiratory complaints include cough, dyspnea, pleuritic pain, and purulent sputum. Bibasilar rales may be heard, but objective physical findings are often minimal in the face of severe toxicity.

Milder types of subacute and chronic pneumonia are often seen. In addition to fever, productive cough, and pleuritic pain, many patients experience marked weight loss and a clinical picture resembling tuberculosis or fungal disease. Secondary skin manifestations are rarely seen unless bacteremia ensues. Physical changes are often subtle but can include localized rales, a pleural friction rub, signs of an effusion, and manifestations of disease localized to soft tissues, lymph nodes, bones, or joints.

Radiologic findings reflect the stage of disease present. In acute fulminant infections, airspace disease can be absent or miliary to larger nodular densities seen in basal segments. In subacute and chronic cases, fibronodular or cavitary apical lesions are found, similar to reactivation tuberculosis.

Diagnostic Features

Melioidosis should be seriously entertained in any febrile patient with a history of residence in a major endemic region such as Southeast Asia or northeast Australia. If sputum is available, the Gram-negative, bipolar-staining bacilli may be seen, and the organisms can be readily cultured and identified in the routine laboratory. Blood and urine cultures are frequently positive in acute cases. In more indolent infections, biopsy may be necessary. Polymerase chain reaction and MALDI-TOF mass spectrometry are increasingly used for diagnosis. Serologic studies can be helpful in active and recrudescent disease, especially in patients residing in nonendemic areas. A specific IgM immunofluorescence test is often positive in recent infections and recrudescent disease. Complement fixation and indirect hemagglutination tests are available and require testing of paired sera over several weeks to confirm active disease.

Differential Diagnosis

In patients from Southeast Asia, acute fulminating infections with pneumonia may be due to traditional bacteria and viruses but may also be caused by infection with *Y. pestis* (plague) and *F. tularensis* (tularemia) (see above). Chronic forms of melioidosis resemble tuberculosis and fungal infections such as histoplasmosis and blastomycosis. Occupation, travel, and history of respiratory illness should help to clarify the cause.

Treatment and Prevention

Recommendations for therapy of acute septicemic melioidosis must be couched in cautious statements. During the Vietnam War, mortality greater than 50% occurred, even with use of three-drug regimens in massive doses. In subacute and chronic pneumonias and recrudescent disease, cure rates approach 100%. Treatment must be prolonged and surgical intervention for drainage or removal of cavitary lesions is sometimes necessary to prevent relapse.

Imipenem, meropenem, or the third-generation cephalosporin ceftazidime in high doses are considered first-line therapy. Some centers add trimethoprim/sulfamethoxazole for better intracellular activity and as a means to potentially decrease the emergence of antimicrobial resistance with combination therapy. Once a good clinical response is seen—usually after at least 2 weeks, and longer if bacteremia or lobar pneumonias are present (3–4 weeks per the Darwin melioidosis treatment guideline[82])—oral therapy may be initiated; this subsequent eradication therapy is considered necessary for preventing recrudescence or later relapse of melioidosis. Eradication regimens are varied and include such agents as trimethoprim-sulfamethoxazole, doxycycline, chloramphenicol, and (less effective) azithromycin and ciprofloxacin. Amoxicillin–clavulanic acid may be used in children. A trial in 140 subjects in Thailand showed that trimethoprim-sulfamethoxazole alone is as effective as and better tolerated than cotrimoxazole plus doxycycline for the eradication treatment of melioidosis.[83] With the exception of kanamycin, other aminoglycosides are ineffective.

No prophylactic antimicrobial studies are available, and no vaccine has been developed. People traveling, living, or working in endemic regions should be advised of this soil- and water-dwelling organism. Traumatic injuries should be avoided, and wounds contaminated with soil or stagnant water should be assiduously cleaned.

■ *Coxiella burnetii* (Q fever)

Initially described in abattoir workers in Brisbane, Australia, in 1935 as Q (for query) fever, Q fever generally causes systemic symptoms, which can progress to atypical pneumonia, occasionally complicated by ARDS, as well as endocarditis and chronic Q fever. In temperate-zone countries, the prevalence of acute Q fever in patients with CAP ranges from 0% to 2.3%: 1.2% in the United Kingdom, 0.9% in the rest of Europe, and 2.3% in the United States.[84] Among endemic regions, rates vary; in the late 1960s in Riyadh, Saudi Arabia, 8.4% of residents greater than 5 years of age were seropositive,[85] while of those with pneumonia in Greece, the frequency of acute Q fever was 4.7% among 3686 patients with atypical pneumonia.[86] In Israel, a study conducted in 1995 among 346 inpatients with CAP showed that 20 (5.8%) had Q fever pneumonia,[87] and a study in the Spanish Basque region demonstrated a prevalence of 18.8% in patients with CAP.[88] Work in French Guiana showed a prevalence of 24%.[84] Although the Middle East is an endemic region, only 3 soldiers developed Q fever during operation Desert Storm, probably because most troops had very limited or no contact with herds of animals.[89]

Bacteriology, Ecology, Epidemiology, and Pathogenesis

C. burnetii has traditionally been grouped with the Rickettsiae, which also includes typhus and spotted fevers. Recent phylogenetic studies based on 16S rRNA sequence analysis have demonstrated that *C. burnetii* is more closely related to *Legionella*, *Francisella*, and *Rickettsiella*. The organism is now classified in the family Coxiellaceae and order Legionellales in the gamma subdivision of Proteobacteria.[90] *C.* burnetii is an acid-fast, pleomorphic, small coccoid or filamentous organism. It is an obligate intracellular pathogen. Although Gram negative, it is often not detected by Gram stains. *C. burnetii* forms spore-like structures that are highly resistant to even severe environmental conditions; it can survive like this for extended periods, especially in very arid soils.

Q fever exists worldwide, except for New Zealand. The largest outbreak ever described occurred in the Netherlands in 2007 to 2010. Large outbreaks have been reported in Switzerland, Great Britain, Germany, and southern France. In North America, Nova Scotia has been the location of a significant number of cases. There are case reports of Q fever in armed forces personnel returning from Iraq.[91] A series of 357 cases of atypical pneumonia from Chile found that 71 (20%) had Q fever; endemic disease had not previously been described there.[92]

Transmission occurs via contact with contaminated birthing products, unpasteurized milk, meat, and wool, or inhalation of windblown dust from areas contaminated by placentae and other animal products. Inhalation results in much more efficient transmission compared with oral intake. Ticks can facilitate transport to other animals. Transfer between humans has been very rarely described, primarily occurring during autopsies or to healthcare workers.[90] Risk factors for spread among animals include relatively closely located bulk milk small ruminant farms, spread from vermin and companion animals, imported straw, and use of artificial insemination.[93] A classic outbreak was described in 12 poker players in Nova Scotia after exposure to a parturient cat—an entity subsequently termed "poker player's pneumonia."[94]

C. burnetii has two distinct antigenic phases. Phase I and II cells are morphologically identical, although they differ in certain biochemical characteristics including their lipopolysaccharide composition. Organisms isolated from infected animals or humans express phase I antigens and are very infectious; the ID50 (number of bacilli needed to infect 50% of individuals) is considered to be 1 to 10, making it among the most infectious agents known.[95] Organisms expressing phase II antigens are less infectious and are recovered after the bacteria have been repeatedly passaged in cell cultures or eggs. Experimentally infected animals and humans first produce antibodies to phase II antigens and later produce antibodies to phase I antigens, which may be used to distinguish acute from chronic infections.

Monocytes and macrophages are the target cells for *C. burnetii* infection. Phagocytosis of *Coxiella* creates phagolysosomes in which the organisms can persist and multiply. The formation of pseudopodal extensions and transient reorganization of filamentous actin are stimulated by virulent (but not avirulent) bacteria. Cell-mediated immunity and granuloma formation is important for control of primary infection. Chronic Q fever is characterized by defective cellular immunity; lymphocytes from patients with Q fever endocarditis do not proliferate in response to *C. burnetii* antigen compared with lymphocytes from those with acute Q fever.[90] Severe inflammation is common with Q fever endocarditis, characterized by upregulated levels of TNF and IL-6 (two inflammatory cytokines), type II TNF receptors, and IL-1 receptor antagonist.[90]

Clinical and Radiologic Features

The incubation period can be as long as 2 to 3 weeks, stressing the importance of recent travel and exposure history. Acute symptomatic infection develops in 40% of patients, while 60% are asymptomatic.[90] Illness may present acutely, with fever, severe headache, arthralgias, myalgias, cough, and other influenza-like symptoms.[96] Q fever can cause endocarditis, hepatitis, and pneumonia. Unlike the other rickettsial diseases, Q fever primarily affects the lungs, with pneumonia in approximately half of cases. The combination of pneumonia and hepatitis should suggest Q fever. Rashes are rare, unlike in the other rickettsial diseases. There can be variation in the predominant symptoms, with pneumonia more common in some outbreaks, and hepatitis more common in others, perhaps due to strain variation or the method of inoculation (ingestion versus inhalation).[90]

Chest radiograph findings are nonspecific. Pleural effusion may be present, as may pericardial effusion. In the 1989 West Midlands outbreak, 10% of chest radiographs were normal, and the features seen on 62 abnormal films were varied; there were no specific aspects to help distinguish Q fever pneumonia from other pneumonias.[97] Complete radiographic resolution frequently took up to 6 months. In another series in the north of Spain, 87% of patients had a single lobar or segmental alveolar opacity, most commonly in the lower lobes, and chest radiographs returned to normal in 70% of patients within 2 months.[98]

Diagnosis and Differential Diagnosis

Sputum is infrequent and often nondiagnostic. Diagnosis of Q fever is most commonly made in patients with epidemiologic risk and confirmed by serology using an immunofluorescence assay against phase II (acute infection) and phase I (chronic infection) antigens, comparing acute and convalescent samples. Seroconversion usually occurs by 7 to 15 days after the onset of clinical symptoms, with roughly 90% of patients seropositive by 3 weeks.[96] A significant number of persons are exposed and never develop symptoms. In one series, sera of 268 people living or working on 111 dairy goat farms in the Netherlands were tested for *C. burnetii* IgG and IgM antibodies using immunofluorescence assay: the seroprevalence in asymptomatic farmers, spouses, and children (12–17 years) was 73%, 67%, and 57%, respectively.[99] In work done to develop models for disease prediction in the outbreak in the Netherlands, male sex, fever, and pneumonia were strong positive predictors of acute Q fever, while cough was a strong negative predictor.[100]

C. burnetii can be cultivated in embryonated eggs, laboratory animals, and in vitro cell culture systems. It must be cultured in biosafety level 3 laboratories due to its extreme infectivity; thus, culture is challenging and not readily available. Molecular diagnostics are increasingly useful, especially for early diagnosis of acute Q fever; *C. burnetii* DNA becomes undetectable in serum as the serologic response develops. With hepatitis, liver biopsy may show the classic granulomas with open space surrounded by a dense eosinophilic fibrin ring, called "doughnut granulomas" (which can also be seen with *Brucella*, *Salmonella*, CMV, Epstein-Barr virus, leishmaniasis, Hodgkin and non-Hodgkin lymphomas, and immune disorders).[101] In the placenta, organisms can be identified in exudates or areas of inflammation using a modified Ziehl–Neelsen, Gimenez, Stamp, Giemsa, or modified Koster stain.

The blood leukocyte count may be elevated in 25% of cases[96] but is less commonly elevated than with routine community acquired pneumonia.[84] Elevations in the erythrocyte sedimentation rate, liver enzymes, and creatine phosphokinase, as well as thrombocytopenia, may be seen.[96] Autoantibodies sometimes develop, including antimitochondrial and anti–smooth muscle antibodies and antibodies to phospholipids (i.e., anticardiolipin or lupus anticoagulant).

Given the relatively nonspecific findings with Q fever, the differential diagnosis is broad, appropriately narrowed based on epidemiology. For pneumonia, other diagnoses would include atypical pathogens such as *Chlamydophila pneumoniae*, *Chlamydia psittaci*, *Francisella tularensis*, *Legionella pneumophila*, and *Mycoplasma pneumoniae*. Viral etiologies also may mimic Q fever. A case report from Turkey describes Q fever mimicking Crimean-Congo hemorrhagic fever.[102]

Treatment and Prevention

Treatment usually involves the use of doxycycline, although fluoroquinolones or rifampin also are effective, and trimethoprim-sulfamethoxazole can be used in pregnant women and children.[90] In chronic Q fever, recommended treatment in adults is at least 18 months of doxycycline given with an alkalizing agent like hydroxychloroquine (added to neutralize the acid environment of the phagosome).

A whole-cell vaccine for Q fever (Q-Vax), developed in Australia, protects humans in occupational settings with a vaccine efficacy of 94%;[103] this vaccine is not commercially available in the United States. Prior to vaccination, patients should be tested for previous exposure to *C. burnetii*; those with previous exposure should not receive the vaccination because of severe local reactions. Vaccination of farm animals against Q fever is effective in curtailing spread.

CONCLUSIONS

Many of the infectious diseases that affect humans originate in animals and enter the human host directly from contact with the animal, from an animal intermediary, or from environmental material contaminated with animal parts or waste. Animals too can acquire infections from contact with humans: "anthroponoses." The crossover of microorganisms between species—pathogenic in some and nonpathogenic in others—highlights the importance of the relationships that humans have with domesticated and nondomesticated animals. Climate change, ecotourism, global transport of goods, and changes in areas of human habitation all contribute to the cross-species transmission of disease. New zoonotic diseases are frequently identified, and the key to recognizing new infectious syndromes requires a thorough understanding of patients' animal and environmental exposures. "One Health" is a global collaborative, multisectoral, and transdisciplinary approach to disease that recognizes the interconnection between people, animals, plants, and their shared environment.[104] We are only beginning to understand the role of animal contact on the human microbiome and the effect that alterations in the gut microbiome have on human disease. As tools for diagnosing infectious diseases caused by pathogens that cannot be seen microscopically or grown in vitro become more readily available and more sophisticated, we are bound to discover more zoonotic and anthroponotic diseases.

CHAPTER 139

Respiratory Failure: An Overview

Michael A. Grippi

Respiratory failure is a condition in which the respiratory system fails in one or both of its gas-exchanging functions—that is, oxygenation of, and carbon dioxide elimination from, mixed venous (pulmonary arterial) blood. Hence, respiratory failure is a syndrome rather than a disease. Many diseases result in respiratory failure, as discussed elsewhere in this volume.

Respiratory failure may be acute or chronic. The clinical presentations of patients with acute and chronic respiratory failure usually are quite different. While acute respiratory failure is characterized by life-threatening derangements in arterial blood gases and acid–base status, the manifestations of chronic respiratory failure are more indolent and may be clinically inapparent.

Although the causes of respiratory failure are diverse, common underlying pathophysiologic mechanisms and management strategies merit a general discussion. This chapter begins with a focus on the definition of respiratory failure and underscores distinctions between acute and chronic varieties. Hypoxemic and hypercapnic respiratory failure are described, and the pathophysiologic underpinnings of each type are reviewed. The concepts of ventilatory supply and demand are considered before an overview of the many categories of disease that result in respiratory failure. Finally, an approach to clinical evaluation and management is outlined, followed by a summary of complications, comments on prognosis, and consideration of sites of care for survivors of respiratory failure who remain "chronically critically ill."

CLASSIFICATION OF RESPIRATORY FAILURE

As noted previously, respiratory failure is characterized by inadequate blood oxygenation or carbon dioxide removal. "Adequacy" is defined by tissue requirements for oxygen uptake and carbon dioxide elimination. In the absence of bedside techniques for direct measurement of these metabolic parameters, clinicians must rely on arterial blood gas values.

Respiratory failure may be classified as *hypercapnic* or *hypoxemic* (Fig. 139-1). *Hypercapnic respiratory failure* is defined as an arterial P_{CO_2} (Pa_{CO_2}) greater than 45 mm Hg. *Hypoxemic respiratory failure* is defined as an arterial P_{O_2} (Pa_{O_2}) less than 60 mm Hg. In many cases, hypercapnic and hypoxemic respiratory failure coexist. Disorders that initially cause hypoxemia may be complicated by respiratory pump failure (see below) and hypercapnia. Conversely, diseases that produce respiratory pump failure are frequently complicated by hypoxemia due to secondary pulmonary parenchymal processes (e.g., pneumonia or atelectasis) or vascular disorders (e.g., pulmonary embolism).

TABLE 139-1 Distinctions Between Acute and Chronic Respiratory Failure

Category	Characteristic
Hypercapnic respiratory failure	Pa_{CO_2} >45 mm Hg
Acute	Develops in minutes to hours
Chronic	Develops over several days or longer
Hypoxemic respiratory failure	Pa_{O_2} <60 mm Hg
Acute	Develops in minutes to hours
Chronic	Develops over several days or longer

Distinctions between *acute* and *chronic* respiratory failure are summarized in Table 139-1. In general, acute hypercapnic respiratory failure is defined as a Pa_{CO_2} greater than 45 mm Hg with accompanying acidemia (pH <7.30).[1] The physiologic effect of a sudden increment in Pa_{CO_2} depends on the prevailing level of serum bicarbonate anion. In patients with chronic hypercapnic respiratory failure—for example, due to chronic obstructive pulmonary disease (COPD)—a long-standing increase in Pa_{CO_2} results in renal "compensation" and an increased serum bicarbonate concentration. A superimposed acute increase in Pa_{CO_2} has a less dramatic effect than does a comparable increase in a patient with a normal bicarbonate level.

Distinction between acute and chronic hypoxemic respiratory failure may not be readily made on the basis of arterial blood gas values.[1] The presence of markers of chronic hypoxemia (e.g., polycythemia or cor pulmonale) provides clues to a long-standing disorder, whereas abrupt changes in mental status suggest an acute event.

An important fact to bear in mind is that even though the definition of hypoxemic respiratory failure rests on measurement of Pa_{O_2}, the major threat of arterial hypoxemia is inadequate tissue oxygenation, reflected in tissue *oxygen delivery.* Tissue oxygen delivery is determined by the product of cardiac output and blood *oxygen content* (Chapter 15); the latter, in turn, depends on hemoglobin concentration and oxygen saturation. Therefore, factors that lower cardiac output or hemoglobin concentration, or inhibit dissociation of oxygen from hemoglobin at the tissue level, may promote tissue hypoxia without technically producing respiratory failure.

PATHOPHYSIOLOGY

Respiratory failure can arise from an abnormality in any of the "effector" components of the respiratory system—central nervous

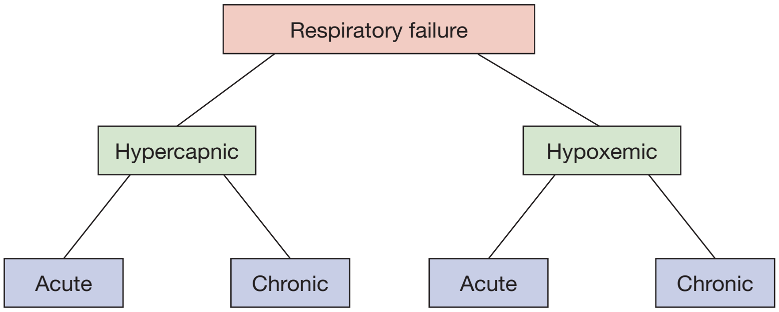

Figure 139-1 Classification of respiratory failure. Although depicted as distinct entities, hypercapnic and hypoxemic respiratory failure frequently coexist. Either may be acute or chronic.

system, peripheral nervous system, respiratory muscles and chest wall, airways, or alveoli (Fig. 139-2). A defect in any of the first four components, which constitute the "respiratory pump," may cause coexistent hypercapnia and hypoxemia; at least initially, disorders of the alveoli are more apt to result in hypoxemia.[2,3]

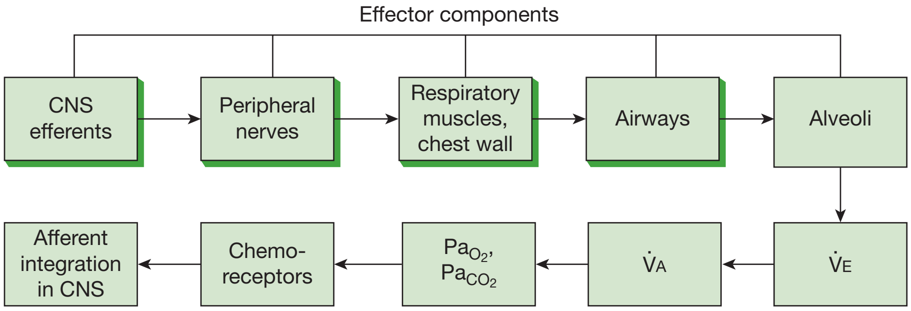

Figure 139-2 Functional components of the respiratory system and its controller. Abnormalities in any of the effector components can result in respiratory failure. The central and peripheral nervous systems, respiratory muscles and chest wall, and airways constitute the "respiratory pump" *(shaded boxes)*. Hypercapnia is the hallmark of respiratory pump failure, while hypoxemia constitutes the primary disturbance in alveolar disorders producing respiratory failure. *(Reproduced with permission from Grippi MA: Pulmonary Pathophysiology. Philadelphia. PA: JB Lippincott; 1995.)*

Hypoxemic Respiratory Failure

As described in Chapters 14–16, four pathophysiologic mechanisms account for the hypoxemia seen in a wide variety of diseases: alveolar hypoventilation, ventilation–perfusion mismatch, shunt, and diffusion limitation.[2] Alveolar hypoventilation occurs in neuromuscular disorders that affect the respiratory system. In the absence of underlying pulmonary disease, the hypoxemia accompanying alveolar hypoventilation is characterized by a normal alveolar–arterial oxygen gradient,[4] as defined by Equation 1:

$$\mathrm{PA_{O_2} - Pa_{O_2} = [PI_{O_2} - Pa_{CO_2}/R] - Pa_{O_2}} \qquad (1)$$

where

$\mathrm{PA_{O_2}}$ = alveolar $\mathrm{P_{O_2}}$
$\mathrm{Pa_{O_2}}$ = arterial $\mathrm{P_{O_2}}$
$\mathrm{PI_{O_2}}$ = inspired $\mathrm{P_{O_2}}$
$\mathrm{Pa_{CO_2}}$ = arterial $\mathrm{P_{CO_2}}$
R = respiratory exchange ratio

In contradistinction, disorders in which any of the other three mechanisms are operative are characterized by widening of the alveolar–arterial oxygen gradient, which is normally less than 20 mm Hg. With ventilation–perfusion mismatching, areas of low ventilation relative to perfusion contribute to the hypoxemia. Similarly, with shunt, either intrapulmonary or intracardiac, deoxygenated mixed venous blood bypasses ventilated alveoli, resulting in "venous admixture." Finally, diseases that increase the diffusion pathway for oxygen from the alveolar space to pulmonary capillary impair oxygen transport across the alveolar–capillary membrane.

Although changes in minute and alveolar ventilation can change $\mathrm{Pa_{CO_2}}$ considerably, this is not so for $\mathrm{Pa_{O_2}}$. Increases in minute ventilation and, secondarily, in alveolar ventilation modestly increase $\mathrm{Pa_{O_2}}$. Indeed, at a $\mathrm{Pa_{O_2}}$ above 55 to 60 mm Hg, the effect of increasing ventilation on oxygen content is minimal, since the oxyhemoglobin dissociation curve is flat in this range.

Hypercapnic Respiratory Failure

At a constant rate of CO_2 production ($\dot{V}_{CO_2}$), $\mathrm{Pa_{CO_2}}$ is determined by the level of alveolar ventilation.[5] The relationship between alveolar ventilation, rate of CO_2 production, and $\mathrm{Pa_{CO_2}}$ is described by Equation 2:

$$\dot{V}_A = K \cdot \dot{V}_{CO_2}/\mathrm{Pa_{CO_2}} \qquad (2)$$

where

$\dot{V}_A$ = minute alveolar ventilation
K = a constant
$\dot{V}_{CO_2}$ = rate of CO_2 production

When $\dot{V}_{CO_2}$ is constant, $\mathrm{Pa_{CO_2}}$ is determined by $\dot{V}_A$, which, in turn, is dictated by two factors: minute ventilation ($\dot{V}_E$) and the relationship between $\dot{V}_E$ and $\dot{V}_A$. The latter is determined by the proportion of $\dot{V}_E$ that constitutes dead space ventilation—that is, the dead space to tidal volume ratio (V_D/V_T):

$$\dot{V}_E = K\,(\dot{V}_{O_2} \cdot RQ)/(\mathrm{Pa_{CO_2}}/[1 - V_D/V_T]) \qquad (3)$$

where

$\dot{V}_{O_2}$ = rate of O_2 consumption
RQ = respiratory quotient (the respiratory exchange ratio in the steady state)
V_D = dead space volume
V_T = tidal volume

Inspection of Equation 3 indicates that disorders reducing $\dot{V}_E$ or increasing the proportion of dead space ventilation may result in hypercapnia.

Ventilatory Supply Versus Demand

A useful theoretical construct for understanding the pathophysiologic basis for hypercapnic respiratory failure is the relationship between ventilatory supply and ventilatory demand (Fig. 139-3).[1]

Ventilatory supply is the maximal spontaneous ventilation that can be maintained without development of respiratory muscle fatigue; ventilatory supply is also known as *maximal sustainable ventilation* (MSV).

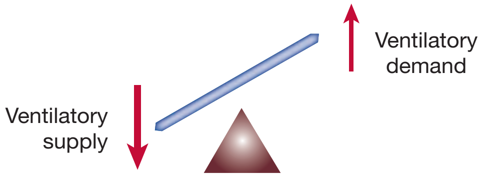
Ventilatory demand is the spontaneous minute ventilation, which, when maintained constant, results in a stable $\mathrm{Pa_{CO_2}}$ (assuming a fixed rate of CO_2 production).

Normally, ventilatory supply greatly exceeds ventilatory demand. Hence, major changes in minute ventilatory requirements (e.g., during exercise) may occur without hypercapnia. In lung disease, significant abnormalities may be present before ventilatory demand encroaches on MSV. Consequently, hypercapnia is a late finding. When ventilatory demand exceeds MSV, $\mathrm{Pa_{CO_2}}$ increases.

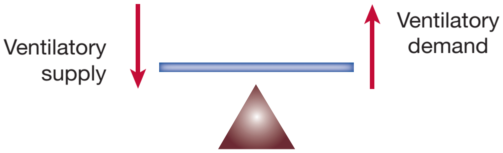
As a general rule, MSV is approximated as one-half the *maximal voluntary ventilation*, or MVV (Chapter 31). A 70-kg adult has an MVV of about 160 L/min, an MSV of 80 L/min, and, under basal conditions, a $\dot{V}_E$ of approximately 6 to 7 liters per minute (90 mL/kg/min). Normally, therefore, there is a 10- to 15-fold difference between resting $\dot{V}_E$ and MSV. In disease states, the $\dot{V}_E$ requirement may approach a markedly reduced MSV. Further reductions in MSV result in ventilatory demand exceeding supply, and hypercapnia occurs.

FACTORS THAT REDUCE VENTILATORY SUPPLY OR INCREASE VENTILATORY DEMAND

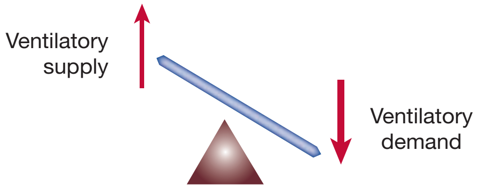
Disruption of any component of the efferent arm of the respiratory control system may diminish ventilatory supply (Table 139-2). While a variety of diseases produce specific abnormalities along the efferent pathway (e.g., phrenic nerve and respiratory muscle disorders), some result in respiratory muscle fatigue—the biochemical,



A Ventilatory supply exceeds ventilatory demand.



B Ventilatory supply equals ventilatory demand.



C Ventilatory demand exceeds ventilatory supply.

Figure 139-3 Relationship between ventilatory supply (maximal sustainable ventilation) and ventilatory demand (overall level of ventilation specified by the CNS controller). Relative size of the arrows indicates levels of supply and demand in each of the three circumstances illustrated. **A.** Normal. Ventilatory supply greatly exceeds ventilatory demand. Physiologic "reserve" is maintained. **B.** Ventilatory supply is decreased and ventilatory demand increased (e.g., acute asthma attack). "Borderline" respiratory failure exists. **C.** Ventilatory demand exceeds ventilatory supply (e.g., sepsis in a patient with COPD). Respiratory muscle fatigue develops, and hypercapnic respiratory failure ensues. See text for details. *(Reproduced with permission from Grippi MA: Pulmonary Pathophysiology. Philadelphia. PA: JB Lippincott; 1995.)*

cellular, and molecular mechanisms of which remain poorly understood.

As described previously, ventilatory demand can be assessed according to Equation 3:

$$\dot{V}_E = K \cdot (\dot{V}_{O_2} \cdot RQ)/(Pa_{CO_2}/[1 - V_D/V_T])$$

Any factor that affects terms on the right-hand side of the equation may result in ventilatory demand exceeding supply. Selected clinical examples are given in Table 139-3.

CATEGORIES OF RESPIRATORY FAILURE

Although many different diseases cause respiratory failure, they may be grouped conveniently according to primary abnormalities in the individual effector components of the respiratory system.[1,2]

Abnormalities of the Central Nervous System

A variety of pharmacologic, structural, and metabolic disorders of the CNS are characterized by suppression of the neural drive to breathe.[3] The resultant hypoventilation and hypercapnia may be acute or chronic.

An overdose of a narcotic or other drug with sedative properties is a common cause of respiratory failure. While the most striking clinical picture occurs with an acute overdose, longstanding use of some agents (e.g., methadone) may result in chronic hypercapnia.

TABLE 139-2 Factors That Diminish Ventilatory Supply

Factor	Clinical Examples
Decreased respiratory muscle strength	
Muscle fatigue	Recovery from acute respiratory failure, high respiratory rates, increased inspiratory time
Disuse atrophy	Prolonged mechanical ventilation, following phrenic nerve injury
Malnutrition	Protein–calorie starvation
Electrolyte abnormalities	Low serum phosphate or potassium concentrations
Arterial blood gas abnormalities	Low pH, low Pa_{O_2}, high Pa_{CO_2}
Fatty infiltration of diaphragm	Obesity
Unfavorable alteration in diaphragm length–tension relationship	Flattened domes of diaphragm caused by hyperinflation
Increased muscle energy requirement or decreased substrate supply	
High elastic work of breathing	Low lung or chest wall compliance, high respiratory rate
High resistive work of breathing	Airway obstruction
Reduced diaphragm perfusion	Shock, anemia
Decreased motor neuron function	
Decreased phrenic nerve output	Polyneuropathy, Guillain–Barré syndrome, phrenic nerve transection or injury, poliomyelitis
Decreased neuromuscular transmission	Myasthenia gravis, use of paralyzing agents
Abnormal respiratory mechanics	
Airflow limitation	Bronchospasm, upper airway obstruction, excessive airway secretions
Loss of lung volume	After lung resection, large pleural effusion
Other restrictive defects	Pain-limited inspiration; tense abdominal distention due to ileus, peritoneal dialysis fluid, or ascites

TABLE 139-3 Factors That Increase Ventilatory Demand

Factor	Clinical Examples
Increased V_D/V_T	Acute asthma, emphysema, late phase of acute respiratory distress syndrome, pulmonary emboli
Increased $\dot{V}_{O_2}$	Fever, sepsis, trauma, shivering, increased work of breathing, massive obesity
Increased RQ	Excessive carbohydrate feeding
Decreased Pa_{CO_2}	Hypoxemia, metabolic acidosis, anxiety, sepsis, renal failure, hepatic failure

Data from Grippi MA: Pulmonary Pathophysiology. Philadelphia. PA: JB Lippincott; 1995.

"Structural" CNS abnormalities producing hypercapnic respiratory failure include meningoencephalitis, localized tumors or vascular abnormalities of the medulla, and strokes affecting medullary control centers. Usually, respiratory failure is observed in the context of other neurologic findings.

A variety of metabolic derangements may produce hypercapnia through depression of respiratory control centers. Examples include severe myxedema, hepatic failure, and advanced uremia. In addition, elevation of P_{CO_2} in the CNS results in neural depression, further enhancing CO_2 retention. A common clinical setting in which elevation of Pa_{CO_2} is observed is chronic metabolic alkalosis (e.g., due to diuretic use), as detailed in Chapter 17.

Finally, obesity hypoventilation syndrome is characterized by hypercapnia due to hypoventilation on a central basis.[6]

■ Abnormalities of the Peripheral Nervous System or Chest Wall

A wide variety of disorders of the peripheral nerves, neuromuscular junction, and chest wall may be associated with hypercapnic and hypoxemic respiratory failure.[3,7–16] While the hallmark is an inability to maintain a level of $\dot{V}_E$ appropriate for the rate of CO_2 production, many of these disorders are complicated by impaired expiratory muscle strength, atelectasis, and aspiration. Through mechanisms outlined previously, hypoxemia develops in conjunction with the hypercapnia.

Among the most common neuromuscular causes of hypercapnic respiratory failure are Guillain–Barré syndrome,[17] myasthenia gravis,[18] polymyositis,[19] the muscular dystrophies, amyotrophic lateral sclerosis (ALS),[20] and a large number of metabolic muscle disorders. In addition, acute poliomyelitis and traumatic spinal cord injury are associated with hypercapnia. Development of respiratory muscle fatigue and atrophy[10,21–23] during prolonged weaning from mechanical ventilation may cause recurrent hypercapnia in the critical care setting.[10,21–25]

Pharmacologic causes of hypercapnia in the intensive care unit are frequently encountered. Early reports on use of depolarizing and nondepolarizing paralyzing agents,[26] particularly in conjunction with systemic corticosteroids (e.g., in management of status asthmaticus) have been well documented; cholinergic crisis during therapy of myasthenia gravis, and administration of aminoglycosides to patients with myasthenia gravis are additional examples.

Primary disorders of the chest wall constitute another important category of neuromuscular respiratory failure. The prototype is severe kyphoscoliosis. Additional examples include flail chest (Chapter 104), extensive thoracoplasty, morbid obesity, and massive abdominal distention due to ascites[27] or distended loops of bowel.

In each of these disorders, a common pathophysiologic sequence develops. Because of inadequate activation of inspiratory muscles or limited thoracic excursion, tidal volume falls. While an increase in respiratory rate compensates initially for the fall in $\dot{V}_E$ (and in $\dot{V}_A$), $\dot{V}_E$ eventually declines. In addition, the sigh mechanism is impaired, which, in conjunction with the low tidal volume, results in atelectasis and reduced lung compliance. Reduced lung compliance produces a further fall in tidal volume and an increase in the elastic work of breathing (Chapter 10). Hence, ventilatory supply becomes limited, while ventilatory demand increases due to a rise in V_D/V_T (as a result of atelectasis and other factors noted below). An imbalance between ventilatory supply and demand arises, and hypercapnia ensues. Furthermore, an impaired gag reflex in the setting of bulbar weakness, coupled with impaired cough due to respiratory muscle involvement, may result in aspiration pneumonia and secondary hypoxemia.

In addition to the pathophysiology described, structural abnormalities of the thoracic cage (e.g., severe kyphoscoliosis, ankylosing spondylitis, thoracoplasty, fibrothorax)[7,28,29] are characterized by an increase in the elastic component of the work of breathing. This results in a higher $\dot{V}_{O_2}$ and a higher proportion of total O_2 consumption by the respiratory muscles (normally, $<5\%$ of $\dot{V}_{O_2}$).

■ Abnormalities of the Airways

Obstructive diseases of the airways—either upper or lower—are common causes of acute and chronic hypercapnia. Examples in the upper airways include acute epiglottitis, aspirated foreign body, tracheal tumor, and narrowing of the trachea or glottis by fibrotic tissue. Disorders of the lower airways include COPD,[30] asthma, and advanced cystic fibrosis. Increasingly, the development of bronchiolitis obliterans, a manifestation of allograft rejection in patients who have undergone lung transplantation, has been recognized as an important cause of respiratory failure.[31]

The underlying mechanisms in airway abnormalities as causes of respiratory failure are multifaceted and variable. However, several common pathophysiologic pathways are operative.

Airway narrowing results in a greater transthoracic pressure gradient requirement for inspiratory airflow. The resistive component of the work of breathing is increased, and the increase is associated with an elevation in $\dot{V}_{O_2}$. In addition, tidal volume falls and dead space ventilation increases. Respiratory muscle fatigue may develop; the consequences of a shallow breathing pattern ensue.

Finally, in some disorders (e.g., acute asthma or an acute exacerbation of COPD), air trapping and lung hyperinflation occur, resulting in diaphragm flattening and worsening diaphragm mechanics (Chapter 10). The overall effect is a growing imbalance between ventilatory supply and demand.[1]

■ Abnormalities of the Alveoli

Although diseases characterized by diffuse alveolar filling frequently result in hypoxemic respiratory failure, hypercapnia may complicate the picture. Common clinical examples in this category include cardiogenic and noncardiogenic pulmonary edema,[32] diffuse pneumonia, extensive pulmonary hemorrhage, aspiration of stomach contents, and near drowning.

Diffuse alveolar filling creates a large right-to-left shunt as pulmonary blood flows through nonventilated or poorly ventilated regions of the lung. In addition, coexisting interstitial edema may impair diffusion across the alveolar–capillary membrane, further impairing oxygenation of mixed venous blood.

In extensive, acute pulmonary disease characterized by alveolar filling, ventilatory demand is high because of hypoxemia and increases in V_D/V_T, the elastic work of breathing (due to reduced lung compliance), the resistive work of breathing (due to airway narrowing and increased airway reactivity), and the neural drive to breathe (mediated by pulmonary parenchymal vagal fibers). In conjunction with heightened ventilatory demand, ventilatory supply is reduced because of alveolar flooding, reduced lung elasticity, respiratory muscle fatigue, and, possibly, reduced blood supply to the diaphragm secondary to shock. Once again, the imbalance between ventilatory supply and demand results in hypercapnia.

APPROACH TO THE PATIENT

The diagnosis of acute or chronic respiratory failure begins with clinical suspicion of its presence. Confirmation of the diagnosis is based on arterial blood gas analysis. Evaluation for an underlying cause must be initiated early, frequently in the presence of concurrent treatment for acute respiratory failure. While the diagnosis of chronic respiratory failure is usually easily established with clinical findings of chronic hypoxemia (with or without findings of hypercapnia), the diagnosis of acute respiratory failure requires more careful analysis.

Signs and symptoms in acute respiratory failure reflect the underlying disease process and associated hypoxemia or acidemia due to hypercapnia. Localized pulmonary findings reflecting the acute causes of hypoxemia (e.g., pneumonia, pulmonary edema, asthma, or COPD) may be readily apparent. Alternatively, the predominant findings may be systemic (e.g., hypotension due to sepsis). The principal manifestations may even be remote from the thorax—for example, abdominal pain in acute pancreatitis, or leg pain due to soft tissue infection complicated by sepsis—each associated with acute respiratory distress syndrome (Chapters 140 and 141). Frequently, neurologic or cardiovascular symptoms and signs predominate. Neurologic manifestations include restlessness, anxiety, confusion, seizures, or coma. Asterixis may be seen with severe hypercapnia. Common cardiovascular findings include tachycardia and a variety of arrhythmias. Finally, there may be few or no findings other than a complaint of dyspnea, as in some patients with hypoxemia due to pulmonary embolism.

Once respiratory failure is suspected on clinical grounds, arterial blood gas analysis is performed to confirm the diagnosis, to assist in the distinction between acute and chronic forms, to assess the magnitude and metabolic impact, and to help guide management (Table 139-4).

PRINCIPLES OF MANAGEMENT

The principles of management of patients in acute respiratory failure include those that are general[2,3,6–8,20,33] and those that are more cause-specific.[30] Triage of the patient to the proper clinical setting, airway maintenance, correction of hypoxemia and hypercapnia, and management of the underlying cause are of paramount importance.

Triage Decisions

The first step in management is to determine the appropriate setting for care—admission to a standard inpatient medical floor or to an intensive or "intermediate care" unit. Factors that constitute the basis for this decision include the acuity of the respiratory failure; the degree of hypoxemia, hypercapnia, and acidemia; the presence of comorbid conditions (e.g., cardiac disease or renal insufficiency); and the clinical direction that the patient takes over the first few minutes or hours of observation. At one end of the spectrum is the patient with fulminant hypoxemic respiratory failure, metabolic acidosis, and imminent cardiovascular collapse, who needs emergent intubation, mechanical ventilation, and admission to a critical care unit. At the other end of the spectrum is the patient with COPD and chronic, compensated hypercapnic respiratory failure, who requires observation in an intermediate care unit or general medical setting.

Airway Management

Assurance of an adequate airway is key in the patient with acute respiratory distress. Whether emergency intubation is required depends on the clinical circumstances described previously. For patients with chronic respiratory insufficiency, the need for intubation also depends on critical arterial blood gas values and the patient's early acute course. When progressive hypoxemia or hypercapnia is observed over the first few minutes or hours of care, intubation and mechanical ventilation are warranted.

However, in recent years, two approaches to acute respiratory failure that might delay or avoid intubation have been investigated: administration of high-flow oxygen (HFO_2) and noninvasive ventilation (NIV).[34–43] These techniques have been evaluated primarily in management of acute hypoxemic respiratory failure, but also in acute hypercapnic failure as well. Additionally, HFO_2 and NIV have been advocated as means of avoiding reintubation in patients with deteriorating respiratory status following surgical procedures.

Contraindications to a trial of noninvasive ventilation include respiratory arrest, ill-fitting face mask, hemodynamic or cardiac instability, patient agitation, swallowing difficulty, excessive respiratory secretions, inability to protect the airway, and recent upper airway or upper gastrointestinal surgery.

Correction of Hypoxemia and Hypercapnia

Once the airway is secured, the clinician must turn attention to the treatment of hypoxemia—the most life-threatening aspect of acute respiratory insufficiency. The goal is to assure adequate oxygen delivery to tissues, generally achieved with a Pa_{O_2} of about

TABLE 139-4 Changes in Arterial Blood Gases, $P_{A_{O_2}}$–Pa_{O_2}, and Ventilation in Acute Respiratory Failure

Failed Respiratory System Component	pH	Pa_{CO_2}	Pa_{O_2}	$P_{A_{O_2}}$–Pa_{O_2}	$\dot{V}_E$	$\dot{V}_A$

[c] *$\dot{V}_E$ declines when frank respiratory muscle failure occurs.*

[d] *Pa_{CO_2} may increase during an exacerbation.*

Data from Grippi MA: Pulmonary Pathophysiology. Philadelphia. PA: JB Lippincott; 1995.

60 mm Hg (assuming an adequate hematocrit and cardiac output). In patients who have coronary or cerebrovascular disease, a slightly higher level of arterial oxygenation may be desirable in order to provide a "buffer" for any sudden, unpredictable changes in gas exchange.

The means by which supplemental oxygen is administered is determined by the clinical circumstances. While some patients may simply require nasal prongs or a face mask to achieve an adequate Pa_{O_2}, others are best treated with controlled-flow oxygen delivered via a Venturi mask—for example, the patient with COPD and chronic hypercapnia (Chapter 40). Generally, if an acceptable level of oxygenation, as judged by arterial blood gases, cannot be attained using a face mask, or if administration of supplemental O_2 causes hypercapnia to worsen significantly (e.g., in some patients with COPD), mechanical ventilation (invasive or noninvasive) is required.

While correcting hypoxemia, the clinician must also address any coexisting hypercapnia and respiratory acidosis. Once again, the immediacy of correction depends on the magnitude of the acidosis and its attendant effects (e.g., elevation of serum potassium). A partly compensated respiratory acidosis in a patient with COPD usually constitutes a less urgent clinical circumstance than does profound respiratory acidosis in a patient with a drug overdose.

Additional management strategies in addressing critically ill patients with acute hypoxemic respiratory failure, including, for example, low-stretch ventilation and prone positioning in ARDS, including that due to COVID-19 infection, and extracorporeal membrane oxygenation (ECMO) are discussed in Chapters 141 and 150, respectively.

■ Search for an Underlying Cause

Finally, as therapy is initiated to correct the hypoxemia, hypercapnia, and acidosis of respiratory failure, a search for the cause of the problem and its management must be undertaken. In some cases, the cause and management are straightforward (e.g., administration of a narcotic antagonist to the patient with a narcotic overdose). In others, a more protracted course may be in store (e.g., long-term ventilator management of fulminant acute respiratory distress syndrome due to sepsis).

In both brief and prolonged cases of respiratory failure, attention to details of management is important in order to minimize the risks of complications of therapy, as discussed in the following section.

MONITORING PATIENTS WITH ACUTE RESPIRATORY FAILURE

Repeated assessment of the patient with incipient or resolving respiratory failure, as well as the patient with frank hypoxemic or hypercapnic failure, is critical in formulating decisions about therapy. Monitoring methods range from routine bedside observations to use of invasive techniques (Chapter 147).

For many patients with acute respiratory failure, simple observation of respiratory rate, tidal volume, use of accessory muscles, and presence of paradoxical breathing movements provides evidence of worsening respiratory failure and the need for intubation and mechanical ventilation. The patient with asthma or an acute exacerbation of COPD will frequently manifest rapid, shallow breathing and paradoxical thoracoabdominal breathing movements as respiratory mechanics deteriorate.[15]

Once placed on mechanical ventilation, the patient must be carefully monitored for ventilator-associated complications (see below). In addition, placement of indwelling arterial and venous catheters, patient immobilization, and use of a broad range of pharmacologic agents present additional potential threats to the acutely ill patient.

While many monitoring techniques are routine and may be universally applicable to patients in a critical care setting (e.g., pulse oximetry), others may be of particular importance in selected clinical circumstances. For example, routine assessment of static respiratory system compliance in a mechanically ventilated patient with acute respiratory distress syndrome or pulmonary fibrosis may provide an early warning of changes in lung edema, atelectasis, or barotrauma.[44] In the patient with status asthmaticus requiring mechanical ventilation, development of hypotension due to intrinsic positive end-expiratory pressure (intrinsic PEEP or "auto-PEEP"),[45] as discussed in Chapter 148, may signal the need to alter ventilator settings or implement sedation or pharmacologic paralysis.

COMPLICATIONS OF ACUTE RESPIRATORY FAILURE

The respiratory patient in a critical care unit must navigate not only the obstacles presented by the underlying pulmonary process, but also the hazards associated with use of mechanical devices and pharmacologic agents. Complications of acute respiratory failure may be broadly categorized as pulmonary, cardiovascular, gastrointestinal, renal, infectious, nutritional, and other (Table 139-5). For details in each of these areas, the reader is referred to chapters elsewhere in this volume.

■ Pulmonary

Common pulmonary complications of acute respiratory failure include ventilator-associated pneumonia ("VAP"),[46–49] ventilator-induced diaphragmatic dysfunction,[23,50,51] critical illness polyneuropathy and myopathy,[52] pulmonary emboli, pulmonary barotrauma, pulmonary fibrosis, and complications directly related to use of mechanical devices.[53,54]

As noted below, pulmonary emboli have been reported in up to one-fourth of patients with respiratory failure in intensive care units. The diagnosis is difficult in this setting, since patients typically have diffuse underlying lung disease, abnormal gas exchange, and many coexisting potential causes for the clinical, radiographic, and physiologic consequences of pulmonary emboli.

Pulmonary barotrauma, identified as the presence of extra-alveolar air in structures that do not normally contain air, may occur in patients receiving mechanical ventilation for a variety of indications, including the acute respiratory distress syndrome.[53] Manifestations of barotrauma include pulmonary interstitial emphysema, pneumothorax, pneumomediastinum, pneumoperitoneum, subcutaneous emphysema, tension lung cysts, and subpleural air cysts.[54] Pulmonary fibrosis may follow acute lung injury associated with acute respiratory distress syndrome. In addition, use of high inspired concentrations of oxygen may enhance development of fibrosis in the presence of acute lung injury.

A strategy of low-stretch ventilation is currently the standard for managing patients with acute lung injury or ARDS and is aimed at minimizing the risks of ventilator-induced injury.[55,56] Use of such a strategy is outlined in the chapters on ARDS (Chapter 141) and mechanical ventilation (Chapter 148). More limited experience has been described using extracorporeal membrane oxygenation (Chapter 150).[57,58]

Common device-related complications include those due to pulmonary artery flotation catheters (Chapter 147), endotracheal intubation, and tracheostomy (Chapter 146).

Additionally, daily interruption of sedative infusions has been shown to reduce duration of mechanical ventilation and length of stay in the ICU.[59–62]

■ Neurologic

Increasingly, neurologic complications of prolonged respiratory failure and mechanical ventilation have been recognized. Two of the most notable are critical illness myopathy and neuropathy, as noted previously, and cognitive disorders. The incidence of cognitive impairment in survivors of ARDS has been reported as high as 70% to 100% at hospital discharge and 20% at 5 years post-discharge. Depression and posttraumatic stress disorder (PTSD) also are common.[63,64]

TABLE 139-5 Complications of Acute Respiratory Failure

- Pulmonary
  - Pulmonary emboli
  - Pulmonary barotrauma (interstitial emphysema, pneumothorax, subcutaneous emphysema, pneumoperitoneum, tension lung cyst, subpleural air cyst)
  - Pulmonary fibrosis
- Related to Use of Mechanical Devices
  - Complications of mechanical ventilation (infection, arterial desaturation, hypotension, barotrauma, others)
  - Complications of insertion and maintenance of pulmonary artery catheter (pneumothorax, air embolism, arrhythmias, infection, thrombosis, pulmonary artery rupture)
  - Complications of tracheal intubation
    - Related to prolonged intubation attempt (hypoxemic brain injury, cardiac arrest, seizures, others)
    - Related to right main bronchus intubation (hypoventilation, pneumothorax, atelectasis)
    - Self- or inadvertent extubation
    - Endotracheal tube dislodgment
    - Endotracheal tube cuff leak
    - Injury to pharynx, larynx, trachea
  - Complications of tracheotomy (pneumothorax, bleeding, tube dislodgment, tracheoinnominate fistula, tracheoesophageal fistula, tracheal stenosis)
- Gastrointestinal
  - Hemorrhage (including "stress" ulceration)
  - Ileus
  - Diarrhea
- Cardiovascular
  - Hypotension
  - Arrhythmias
  - Decreased cardiac output
  - Myocardial infarction
  - Pulmonary hypertension
- Renal
  - Acute renal failure
  - Fluid retention
- Infectious
  - Nosocomial pneumonia
  - Bacteremia
  - Sepsis
  - Paranasal sinusitis
- Nutritional
  - Complications of underlying malnutrition (decreased respiratory muscle strength, immune suppression, others)
  - Complications of enteral feeding (pneumothorax, pleural effusion, sinusitis, aspiration, diarrhea)
  - Complications of parenteral feeding (pneumothorax, sepsis, hyperglycemia, hyperosmolar coma, hypophosphatemia, liver function test abnormalities)
  - Complications of refeeding (hypercapnia)
- Other
  - Psychiatric (anxiety, depression, confusion, sleep dysfunction, psychosis)
  - Hematologic (anemia, thrombocytopenia)

■ Cardiovascular

Common cardiovascular complications in patients with acute respiratory failure include hypotension, reduced cardiac output, arrhythmias, pericarditis, and acute myocardial infarction. These complications may be related to the underlying disease process, mechanical ventilation, or use of pulmonary artery flotation catheters.

While venous and, less commonly, arterial thromboemboli are well-known complications of prolonged immobility in mechanically ventilated patients in an ICU, recent experience with an acquired coagulopathy in patients with ARDS due to COVID-19 infection has modified approaches to prophylaxis and treatment.[65,66]

■ Gastrointestinal

A variety of gastrointestinal complications of acute respiratory failure, particularly during mechanical ventilation, have been well described.[67] The major ones include hemorrhage, gastric distention, ileus, diarrhea, and pneumoperitoneum. "Stress" ulceration is extremely common in patients with acute respiratory failure. Associated risk factors include trauma, shock due to a variety of causes, sepsis, renal failure, and liver disease.

■ Infectious

Nosocomial infections are a frequent complication of acute respiratory failure. Principal among these are pneumonia, sepsis, and urinary tract infections. Each typically occurs with the use of mechanical devices, including endotracheal and tracheotomy tubes, indwelling central venous and pulmonary artery catheters, and urinary bladder catheters.

The incidences of VAP and ventilator-associated tracheobronchitis (VAT)[68–71] in the critically ill are significant. The incidence of VAP is estimated to be as high as 5.8 cases per 1000 ventilator days and is particularly prevalent in those with ARDS. The need for prolonged mechanical ventilation is a harbinger for development of VAP. Not unexpectedly, VAP occurring in the medical intensive care unit is associated with a significantly increased length of stay and higher mortality. Guidelines have been developed for treatment of patients with VAP.[72–76]

■ Renal

Acute kidney injury, previously referred to as acute renal failure, and abnormalities in electrolyte and water homeostasis are not uncommon in critically ill patients with acute respiratory failure; the former may be seen in up to 60% of patients in intensive care units. Development of acute kidney injury in a patient with acute respiratory failure carries a poor prognosis and a high mortality. The causes of acute kidney injury are numerous and include sepsis or septic shock, cardiogenic shock, hypovolemia, cardiac or extensive gastrointestinal surgery, administration of nephrotoxic drugs, hepatorenal syndrome, and urinary obstruction, among others.[77]

In the case of critical illness due to COVID-19, a high incidence of renal disease has been recognized.[78,79]

■ Nutritional

Nutritional complications of acute respiratory failure include the effects of malnutrition on respiratory performance and complications related to the administration of enteral or parenteral nutrition.[80–82] Complications of enteral nutritional support relate to initial insertion of the catheter (e.g., tracheal or pleural space penetration, pneumomediastinum, pneumothorax, pleural effusion) and its maintenance (e.g., paranasal sinusitis, aspiration). In addition, vomiting, abdominal distention, and diarrhea are common.

Complications of parenteral nutrition are mechanical (e.g., pneumothorax during catheter insertion), infectious (e.g., catheter-related sepsis), or metabolic (e.g., metabolic acidosis, hyperglycemia and hyperosmolar coma, hypophosphatemia). Hypercapnia, induced by enteral as well as parenteral nutrition, can complicate management of patients who have limited ventilatory reserve.

PROGNOSIS

Interpretation of studies addressing the prognosis of patients with acute respiratory failure is subject to a number of constraints, including marked clinical variability in the patients studied, predominance of studies from intensive care units in large university teaching hospitals, and variability in treatment methods employed over the time span of studies performed. In addition, many studies report only hospital mortality, not long-term survival or quality of life. Finally, findings from large-population studies are difficult to extrapolate to prediction of outcome in a single patient. Nonetheless, several generalizations can be made regarding the prognosis of patients hospitalized with acute respiratory failure.

■ Morbidity and Mortality in Acute Hypoxemic Respiratory Failure

As expected, mortality in hypoxemic respiratory failure depends on the underlying cause. A number of studies have addressed outcome in patients with ARDS.

Mortality in ARDS appears to have improved in recent years, but it remains high in the elderly; for those 85 years of age or older, mortality is 60%.[83] Patients who develop sepsis after trauma have a lower mortality than do patients with sepsis that complicates medical disorders. Notably, patients with pre-existing lung disease, higher $F_{I_{O_2}}$ or PEEP requirements, or a lower Pa_{O_2} may not necessarily have a poorer chance of survival. Early experience with ARDS due to COVID-19 suggested an extremely high mortality, but mortality rates seen later in the pandemic were not as high. The improvement may reflect use of better treatment strategies, including timing of intubation, application of prone positioning, and use of selected therapeutics, including corticosteroids.[84,85]

Although earlier studies indicated that many patients who survived an episode of ARDS manifested some impairment of pulmonary function, including obstructive and restrictive defects and reduction in diffusing capacity, 1 or more years after recovery,[86] more recent data show good preservation of lung function 5 years following survival from ARDS. In fact, lung function is usually normal or near normal, especially in young patients.

Despite recovery of pulmonary function, many survivors of ARDS have persistent functional disabilities after discharge, largely related to muscle wasting and weakness.[87] As noted previously, many survivors of ARDS have neurocognitive findings at hospital discharge, and in a significant number, the deficits persist long term.[87–91]

■ Morbidity and Mortality in Acute Hypercapnic Respiratory Failure

In general, several parameters presage a higher mortality in patients admitted with hypercapnic respiratory failure: (1) the patient's "physiologic reserve," as determined by concurrent cardiopulmonary, renal, hepatic, or neurologic disease and the patient's age; (2) the underlying cause of the acute deterioration; (3) the severity of the respiratory failure, as defined by arterial pH and P_{CO_2}; and (4) development of complications after onset of acute respiratory failure—for example, sepsis, pneumonia, renal failure, or gastrointestinal bleeding.

For patients hospitalized with an acute exacerbation of COPD, overall mortality is 8% to 12%, but it may be as high as 28% for those with significant comorbidities;[92,93] mortality for this group at 1 year is 43%.[93] For patients with an acute exacerbation of COPD who require mechanical ventilation, in-hospital mortality is high; 1-year mortality approaches 25%, and 5-year mortality 70%.[30,87–91]

■ Post-Acute Care Options for Survivors with Chronic Critical Illness

With increasing numbers of patients surviving acute, catastrophic illness or complications of advanced surgical procedures, long-term ventilator dependency and "chronic critical illness" have become challenging clinical issues. This group of patients requires complex medical management and generates considerable debate over medical ethics and healthcare costs. One relatively recent development related to management of chronically critically ill patients is the growth of long-term acute care hospitals—LTACHs.

LTACHs are either free-standing facilities or are based on the concept of a "hospital within a hospital." They focus on management of a wide variety of medically complex patients and typically include a significant cohort of those who are ventilator-dependent. Medicare provides a DRG payment to the LTACH that is separate from that to the acute care facility from which the patient is transferred. Fairly precise rules constitute admission and discharge criteria and, thereby, determine the average length of stay at the LTACH (25 days or greater).[94]

Data on long-term survival and functional status for ventilator-dependent patients discharged from LTACHs are striking. For those who are admitted and subsequently discharged with ventilator dependency (i.e., patients who are not successfully liberated), mean survival post-discharge is 100 days.[95] Furthermore, overall 1-year survival is 56%, with only 9% of patients reporting independent functioning 1 year after discharge.[96]

SECTION 15 Lung Failure

CHAPTER 140

Acute Respiratory Distress Syndrome: Pathogenesis

Asha N. Chesnutt
Michael A. Matthay

INTRODUCTION

This chapter focuses on the pathogenesis of the acute respiratory distress syndrome (ARDS). Chapter 141 discusses clinical features and management of these disorders.

A 1994 consensus conference defined the spectrum of acute lung injury (ALI)/ARDS as follows: (1) ALI, defined as arterial hypoxemia with a $\text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2}$ less than 300, and ARDS, defined as a $\text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2}$ less than 200, accompanied by (2) bilateral pulmonary infiltrates, and (3) absence of left atrial hypertension.[1] A more recent report, based on the so-called Berlin definition, recommends identification of three categories of ARDS, based upon the degree of hypoxemia alone: (1) mild ARDS ($200 < \text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2} \leq 300$ mm Hg), (2) moderate ARDS ($100 < \text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2} \leq 200$ mm Hg), or (3) severe ARDS ($\text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2} \leq 100$ mm Hg).[2] For the purposes of this chapter, both ALI and ARDS will be referred to as ARDS.

A recent comprehensive review of ARDS provides extensive references and illustrations relevant to epidemiology, definitions (including pediatric ARDS), pathogenesis based on experimental and clinical studies, management strategies, and long-term complications of ARDS.[3]

PATHOPHYSIOLOGY OF PULMONARY EDEMA IN ACUTE RESPIRATORY DISTRESS SYNDROME

Pulmonary edema occurs when fluid is filtered into the lungs faster than it can be removed. Accumulation of fluid may have major consequences on lung function because efficient gas exchange cannot occur in fluid-filled alveoli. Lung structure relevant to edema formation and the forces governing fluid and protein movement in the lungs have been the subject of classic and more recent reviews.[4,5]

Vascular Fluid and Protein Exchange

The essential factors that govern fluid exchange in the lungs are expressed in the Starling equation for the microvascular barrier:

$$\text{Jv} = \text{LpS}[(\text{Pc} - \text{Pi}) - \sigma\text{d}(\pi\text{c} - \pi\text{i})]$$

where

Jv = the net fluid-filtration rate (volume flow) across the microvascular barrier
Lp = the hydraulic conductivity (permeability) of the microvascular barrier to fluid filtration (a measure of how easy it is for water to cross the barrier)
S = the surface area of the barrier
Pc = the pulmonary capillary (microvascular) hydrostatic pressure
Pi = the interstitial (perimicrovascular) hydrostatic pressure
πc = the capillary (microvascular) plasma colloid osmotic (or oncotic) pressure
πi = the interstitial (perimicrovascular) fluid osmotic pressure
σd = the average osmotic reflection coefficient of the barrier (a measure of the effectiveness of the barrier in hindering the passage of solutes from one side of the barrier to the other)

The Starling equation predicts the development of two different kinds of pulmonary edema. *Increased pressure pulmonary edema* occurs when the balance of the driving forces increases, forcing fluid across the barrier at a rate that can no longer be accommodated by lymphatic drainage. *Increased permeability pulmonary edema* occurs in the presence of ARDS that damages the normal barriers to fluid filtration and allows increased flux of liquid and protein into the extravascular compartments of the lungs. Congestion, atelectasis, and pulmonary edema were features of the original description of the syndrome.[6]

Thus, pulmonary edema results from increases in either hydrostatic driving pressures (increased pressure edema) or barrier conductance (increased permeability edema), or both. What distinguishes the two types is barrier permeability, which is normal in increased pressure edema, but abnormal in increased permeability edema. Fluid flow into the lungs is driven across the barrier in both types of edema by the balance of pressures. ARDS results primarily from an increase in lung vascular permeability, although some cases may be made worse by the presence of elevated lung vascular hydrostatic pressures.

Increased Permeability Pulmonary Edema

Increased permeability pulmonary edema is caused by an increase in liquid and protein conductance across the barriers in the lungs. The essential feature is that the integrity of the barrier to fluid and protein flow into the lung interstitium and alveoli is altered. Increased permeability edema is sometimes called *noncardiogenic pulmonary edema*, and the resulting clinical syndrome is ARDS.

Accumulation of fluid and protein increases when the lung endothelial and epithelial barriers are injured. If the rate of fluid accumulation exceeds the rate at which it can be removed, increased permeability edema occurs. Large animal models employing measurements of hemodynamics and lung lymph flow demonstrate that clinically relevant causes of ARDS, including live bacteria, endotoxin, and microemboli, induce an increase in lung vascular permeability that causes protein-rich lung edema.[7–9] Because the barriers limiting fluid and protein flow into the lungs do not function normally when the lungs are injured, the lungs are not protected against edema by the usual safety factors. Although increases in fluid and protein filtration across the lung endothelium can be removed by lymphatics and drained away from the alveolar walls as in increased pressure edema, much more fluid and protein are filtered at any given sum of driving pressures, since the barriers to flow are much less restrictive than normal.

Edema formation in injured lungs is sensitive to hydrostatic driving pressures. Driving pressures are often increased when the lungs are injured because of the vasoconstrictive effects of inflammatory mediators, such as thromboxanes. Thromboxanes may shift the main site of vascular resistance to postcapillary venules, thus increasing hydrostatic pressure at the microvascular fluid exchange sites, or may exert cardiac effects. For example, elevated left atrial pressure, pulmonary venoconstriction, or an increase in cardiac output in sepsis may increase hydrostatic pressure at the microvascular fluid exchange sites. Although a primary event in ARDS is an increase in lung vascular permeability, the magnitude of lung edema formation in ARDS may be substantially increased when lung vascular pressures and volume are elevated, consistent with the effects of elevated hydrostatic pressure on transvascular flux of fluid and protein.

Because the lung endothelial and epithelial barriers are injured in ARDS, the protective effects of protein osmotic pressure differences across them are lost; driving pressure is unopposed by protein osmotic pressure, and even normal hydrostatic pressure results in significant fluid and protein extravasation into the interstitial and alveolar spaces. The ability of the lymphatics to pump the excess filtrate away is increased when the lungs are injured. If the alveolar epithelial barrier is damaged, edema may accumulate readily in alveoli, since most of the resistance to fluid and protein flow into the alveoli is in the epithelial barrier.

To summarize, the majority of patients with ARDS have normal or low hydrostatic pressures and increased alveolar-capillary permeability. However, up to 30% of patients with ARDS may have an elevated left atrial pressure.[10] Lung fluid balance is a dynamic concept that incorporates both formation and removal of edema fluid in the interstitium and airspaces.

Lung Physiology

The effects of increased permeability edema on lung mechanics and gas exchange depend, in part, on the magnitude of edema accumulation. As with increased pressure edema, the major effects on pulmonary mechanics occur with alveolar flooding.

About 20% to 30% of the extravascular water of the lungs is in the extravascular interstitial tissue. This volume can more than double before alveolar flooding occurs. In experimental lung injury, functional residual capacity (FRC) is decreased as a consequence of alveolar flooding; the loss of units that can be ventilated accounts for most of the decrease in static lung compliance.[11] Computed tomography has provided new insights into structure-function relationships in human ARDS. In the early stage of lung injury, when alveolar edema predominates, the lungs are characterized by a more homogeneous alteration of vascular permeability, and edema may accumulate evenly in all lung regions, with a nongravitational distribution. Later in the exudative phase of ARDS, the consolidation is more gravity-dependent. In the organizing phase, lung reticulation appears.

Measurements of pulmonary mechanics in mechanically ventilated patients with ARDS show a decrease in static lung compliance as a consequence of loss of ventilated lung units. In addition, airflow resistance is increased as a result of decreased lung volume.[12] Bronchospasm may add to the increase in airflow resistance and may be partially reversed in some patients by administration of inhaled bronchodilators. Chest wall compliance is reduced, probably because of alterations in the intrinsic mechanical properties of the chest wall by abdominal distention, chest wall edema, and pleural effusion. Respiratory mechanics and responses to positive end-expiratory pressure (PEEP) during mechanical ventilation in patients with ARDS originating from pulmonary disease (e.g., pneumonia and associated lung consolidation) and those arising from extrapulmonary disease may differ.[13]

The injured lung in ARDS may release biologically active substances that can interfere with the normal state of low surface tension in the alveoli. In addition, activated neutrophils may reduce surfactant function in vitro and degrade major surfactant apoproteins through a combination of proteolysis and oxidant radical-mediated mechanisms. Human lung surfactant obtained from bronchoalveolar lavage (BAL) fluid in patients at risk for ARDS and from those with established ARDS are abnormal in chemical composition and functional activity.[14] Abnormalities may also be caused by interactions between surfactant and edema proteins, since plasma proteins interfere with surfactant function.

Gas exchange is severely compromised in increased permeability edema, because of both intrapulmonary shunting of blood and ventilation–perfusion inequalities. Clinical evidence indicates that patients with early ARDS have a marked increase in pulmonary dead space fraction.[15] This finding indicates that many ventilated lung units are not well perfused, although intrapulmonary shunting may also contribute to the elevated dead space. Minute ventilation is typically twice normal (approximately 12 L/min) at the onset of ARDS. The subject of gas exchange in ARDS has been recently reviewed.[16]

Pathologic Findings

Based on several studies that included a preponderance of postmortem pathology, the light and electron microscopic appearances of human and animal lung tissue in ARDS have been described.[17] The earliest changes are marked by widespread alveolar and interstitial edema, inflammation, and hemorrhage. This phase is the exudative phase of ARDS. Hyaline membranes, composed of precipitated plasma proteins, fibrin, and necrotic debris, are frequently found and constitute the footprint of a pathologic finding termed diffuse alveolar damage (DAD), which pathologists use to define ARDS microscopically (Fig. 140-1).[18]

The alveolar epithelium may be more extensively damaged than is the vascular endothelium. Alveoli that demonstrate widespread destruction of type I alveolar epithelial cells may appear adjacent to normal alveoli. The injured alveolar epithelium is swollen, disorganized, and, frequently, detached from basement membranes. The alveolar surface may be covered by hyaline membranes. Type I cells are more severely damaged than type II cells. The thin cytoplasmic extensions of cells far from the nucleus, which cover the thin side of the alveolar-capillary barrier, may be most severely affected. The interstitium is widened by edema (especially in peribronchovascular cuffs) and may be filled with leukocytes, platelets, red blood cells, fibrin, and debris (especially near the alveolar walls). The microvascular endothelium may show cytoplasmic swelling or vacuoles and greater numbers of intraluminal leukocytes.

After about 5 to 10 days, the exudative phase of ARDS is followed by a proliferative phase. The relative contributions of the original insult, repair processes, and effects of therapies on this and subsequent phases are not well known. Some abnormalities occurring after the initial exudative phase are related to effects of traditional modes of mechanical ventilation that used tidal volumes between 12 and 15 mL/kg predicted body weight.

Reabsorption of some of the edema fluid characterizes the proliferative phase. Fibrin may be prominent in alveoli and interstitium, and infiltration with inflammatory cells and fibroblasts, which may have been activated very early in the course of lung injury, may be seen. The alveolar epithelium is often cuboidal and made up largely of proliferating type II cells. The air–blood barrier may be thickened by interstitial and epithelial enlargement. The pulmonary vascular bed may be partially or completely disrupted, and structural alterations may reduce its surface area.

In a study addressing the clinicopathologic correlation of the new Berlin definition of ARDS severity with historic autopsy data, a greater proportion of patients with severe ARDS demonstrated histopathologic findings of DAD compared with those with mild or moderate disease.[19] The final or fibrotic phase does not occur in all patients but has been linked to prolonged mechanical ventilation.

Experimental Studies

The most common clinical disorders associated with the development of ARDS are pneumonia, sepsis, gastric aspiration, and major

FIGURE 140-1 **A**. trauma. Other, less common causes include transfusion-associated lung injury, drug overdose, severe acute pancreatitis, and near-drowning. The initiating insult to the lungs occurs via either the airways or the bloodstream.

The exact mechanisms by which the lungs are injured have been studied in humans, animals, and cellular systems. Human studies have provided descriptive data regarding the events that occur in the airspaces before and after the onset of lung injury. Studies using BAL or collection of pulmonary edema fluid in patients following the onset of ARDS have demonstrated a major acute inflammatory response, which begins prior to clinical recognition of ARDS.[20] The response peaks during the first 1 to 3 days of clinically defined ARDS and resolves slowly over 7 to 14 days in patients who remain intubated. These studies have shown the complexity of the evolving inflammatory responses, characterized by accumulation of acute response cytokines and their naturally occurring inhibitors, oxidants, proteinases and antiproteinases, lipid mediators, growth factors, and the collagen precursors involved in the repair process.

Hypotheses regarding the mechanisms of lung injury have been tested in animal models and in vitro studies, and several reviews have summarized the findings.[4,9] The existing animal models do not completely reproduce all of the aspects of ARDS in humans, in part because human ARDS evolves over a longer period of time than can be studied in the laboratory. In addition, the lungs of humans are exposed not only to the initial injurious insult, but also to the therapies that are used to treat ARDS, such as mechanical ventilation, fluid resuscitation, and antibiotics. Experiments using isolated cells have been helpful in testing specific concepts, but the complexity and redundancy of intact biologic systems are not reproduced in simplified experimental systems. By design, most experimental work limits study to one causative agent, thereby reducing actual clinical complexity to the simplicity of a single experimental pathway. Increased permeability edema in humans is likely to be caused by interactions among a number of different pathways acting in parallel or series, and modulated by process of care variables such as mechanical ventilation, fluid management, vasopressor use, and several comorbidities, including diabetes mellitus, alcohol and cigarette exposure, and renal and liver disease.[9]

Studies in isolated organs and small animals in which hemodynamic variables are not measured can be difficult to evaluate. Indices of lung injury, usually measured by the appearance of markers in lungs, lavage fluid, or perfusate, are not determined solely by the barrier function of the microvasculature. Indeed, when vascular endothelium is injured, fluid and protein movement from the vascular space into the lungs is sensitive to hydrostatic driving pressures and filtration surface area. Hence, the effects of experimental interventions may be caused by changes in these parameters and not by changes in microvascular barrier function.

The effects of microvascular driving pressures and surface area can be difficult to evaluate, even in large, instrumented animals. In sheep and goats, interpretation of lung lymph fluid and protein flow changes are further complicated by contributions of extrapulmonary lymphatics, physical forces acting on lymphatics, and possible intranodal modification of lymph. Data from experimental animal models suggest that at least two broad categories of mechanisms of ARDS are operative: (1) those that are *indirect* (i.e., require the participation of intermediary mechanisms, e.g., host defenses); and (2) those that are *direct* (i.e., do not require intermediary mechanisms; injury probably occurs as a result of contact between an offending substance and lung tissue). These categories overlap, since once the lungs are injured, inflammatory responses occur, which may compound the primary mechanism of injury.

MECHANISMS OF ACUTE RESPIRATORY DISTRESS SYNDROME

The following themes regarding the mechanisms of ARDS are discussed below: infection, inflammation, and direct toxicity. Although discussed separately, they are all interrelated.

■ Role of Infection

ARDS develops in 20% to 45% of patients with severe sepsis. Increased microvascular permeability to albumin has been shown to accompany human sepsis, and infection and the sepsis syndrome are major causes of ARDS in humans. Patients who develop shock in response to known or suspected infection have a particularly high incidence of ARDS, and the mortality of patients with ARDS associated with infection (i.e., sepsis syndrome) is increased. ARDS also appears to predispose the lungs to infection, and delayed infection is an important cause of morbidity in patients who survive the initial lung insult.

The mechanisms by which infection and sepsis syndrome injure the lungs are only partially understood. The lung injury is likely related to factors other than direct damage by bacteria or other microorganisms, since the prognosis appears unrelated to documented bacteremia or pneumonia. In experimental animals, intravenous infusions of live *Pseudomonas aeruginosa*, or endotoxins from *Escherichia coli*, or surgically induced peritonitis result in increased permeability pulmonary edema.[21] ARDS caused by endotoxin in sheep is thought to be an inflammatory response mediated, at least in part, by neutrophils and tumor necrosis factor (TNF). Endotoxin may also affect the clotting system and metabolic functions of the lungs, as well as predispose the lungs to the development of pulmonary infections by increasing adherence of bacteria to injured endothelium. Exoproducts of bacteria, such as elastase and *Pseudomonas* exoenzyme U, also have been shown to injure the lungs.[7] Current evidence supports a primary role of the microcirculation in the pathogenesis of ARDS after sepsis.[3]

Bacterial products may also play a role in pathogenesis of ARDS by sensitizing the lungs to the effects of mechanical stretch. Gram-negative lipopolysaccharide causes an acute inflammatory response in the lungs of humans. Bacterial endotoxin enhances the responses of human alveolar macrophages to positive-pressure ventilation; pretreatment of rats with intravenous endotoxin enhances cytokine production in the lungs during mechanical ventilation ex vivo. Furthermore, mechanical ventilation using moderate or large tidal volumes increases the sensitivity of lung macrophages to endotoxin in vitro and the expression of the endotoxin recognition molecule, CD14, on lung cells in vivo. Endotoxin recognition pathways are increased in the lungs of patients with ARDS, and the biologic effects of endotoxin are amplified in the lungs of patients with lung injury. The synergism between bacterial products and mechanical stretch suggests that interrupting these pathways might limit some forms of ARDS in humans.[22]

Increased permeability edema is associated with impaired antibacterial defenses. In animal models, bacterial infections worsen ARDS. The cause of impaired bacterial defenses in ARDS is not known. Genetic polymorphisms that predispose individuals to the injurious effects of specific bacteria or viruses may influence the development of ARDS. Several polymorphisms are associated with more severe pneumococcal, *Legionella*, and viral lung infections.[23] The genetic factors that regulate the virulence of infecting pathogens also require more research to relate the severity of clinical lung injury to specific microbiologic variables that contribute to severe pneumonia and ARDS.[24]

■ Role of Inflammation

Substantial evidence implicates host defenses and inflammatory responses in the underlying mechanism of ARDS. The balance between protective and injurious innate and adaptive immune responses and hemostatic pathways may determine whether alveolar injury can be repaired and resolved. For example, in lung infection, acute inflammatory responses to pathogens and their toxins cause ARDS through leukocyte protease release, generation of reactive oxygen species, synthesis of chemokines and cytokines, Toll-like receptor engagement, and actions of lipid mediators. However, these same inflammatory mechanisms, when controlled, rather than excessive, are requisite in pathogen containment and clearance.[25–27]

Normally, the pulmonary circulation contains a large pool of marginated neutrophils that change shape in order to squeeze through the lung capillaries. When neutrophils are activated, they stiffen and become less distensible. These neutrophils are retained for longer periods of time in the pulmonary microcirculation. Endothelial activation leads to increased expression of leukocyte adhesion molecules, providing a second mechanism to slow the transit of neutrophils. Trapped neutrophils respond to chemotactic gradients generated by chemokines produced by alveolar macrophages and mesenchymal cells and migrate into the airspaces. Activated neutrophils generate and release toxic substances (e.g., oxygen metabolites and granular constituents, such as proteases, and cationic lysosomal enzymes) that disrupt the function of the microvascular and epithelial barriers. Normally, these barriers limit liquid and protein flow out of the vascular space and into the alveolar spaces, mitigating the development of permeability edema.[22]

Inflammatory responses also have the potential to induce lung cell injury by activating cell death pathways, leading to apoptosis. Bacterial products, such as *Pseudomonas* exoenzyme U and mechanical stretch, may lead to direct cellular necrosis. Apoptosis is mediated by a family of death receptors, including TNF and Fas receptors. The Fas ligand (FasL) is a 45-kDa peptide that is shed from the cell surface by the action of metalloproteinases.[28] Biologically active soluble FasL (sFasL) accumulates in the lungs of patients with ARDS, inducing apoptotic death of human lung epithelial cells in vitro. Human sFasL induces epithelial cell death in the lungs of rabbits; a monoclonal antibody that activates membrane Fas causes alveolar wall apoptosis and fibrosis in the lungs of mice.[28]

Apoptosis and inflammation pathways intersect, as stimulation of membrane Fas induces cytokine production in human macrophages and inflammation in the lungs of rabbits and mice. In addition, lung injury may be able to trigger apoptosis pathways in distant organs, such as the kidney, perhaps by increasing the concentrations of circulating sFasL. Thus, inflammatory responses may trigger cell death pathways, and cell death pathways triggered by sFasL may induce inflammation in the lung alveolar environment. Recent human studies implicate apoptosis as an important mechanism in human lung injury.[29]

Precision medicine has transformed approaches to many disease states including ARDS. Latent class analysis has identified a hyperinflammatory and hypoinflammatory subphenotypes in ARDS. The hyperinflammatory subphenotype is characterized by higher plasma concentrations of inflammatory biomarkers, and some clinical variables including lower platelet counts and lower serum bicarbonate concentrations. Secondary analysis of the NHLBI, ARDS, NET, ALVEOLI, ARMA, and FACTT trials have shown that these subphenotypes respond differently to randomly assigned fluid management.[30,31] The hyperinflammatory subphenotype has elevated levels of interleukin 6 (IL-6), IL-8, and soluble TNFR1. Sepsis and vasopressor use have been more common, and mortality has been higher in the hyperinflammatory subphenotype. A study showed that application of the latent class analysis to a trial of simvastatin for ARDS, which was carried out in the United Kingdom, revealed again that patients segregated into a hyper- or hypoinflammatory subphenotype, with approximately 35% of patients in the hyperinflammatory group.[32] In addition, although the overall results of the trial showed no effect of simvastatin on mortality, this secondary analysis showed that patients in the hyperinflammatory group benefited from simvastatin with a greater 28-day survival—thus raising the possibility that identifying subphenotypes in ARDS might lead to effective pharmacologic therapies.

■ Role of Direct Toxicity

Inflammation is not required for all forms of ARDS. ARDS may develop in neutropenic patients. A clinical trial using granulocyte colony–stimulating factor to increase the number and activation state of circulating neutrophils in patients with severe pneumonia did not reveal an increased incidence of ARDS.[33] Lung injuries that do not require the participation of neutrophils have been described in animal models.

Direct lung injury is also thought to occur in humans. Putative agents that directly injure the lungs include mechanical forces during mechanical ventilation, toxic and corrosive chemicals and gases (e.g., hydrochloric acid, chlorine gas, phosgene), and aspiration of fresh or salt water (near-drowning). Many of these injuries develop rapidly, supporting the idea that injury is caused directly by contact with the respiratory epithelium in the airways or alveolar walls.

ARDS develops in approximately 10% to 30% of critically ill trauma patients. Many investigators have studied air pollution as a risk factor. A recent study showed that among a cohort of patients presenting to a level 1 trauma center, long-term exposures to NO_2, SO_2, CO, and PM 2.5 and ozone were associated with the subsequent development of ARDS.[34] Another study showed that cigarette smoking contributes to ARDS development after trauma by altering community composition of lung microbiotica.[35]

Inflammatory pathways are likely to be rapidly activated following many types of direct lung injury, as probably occurs following aspiration of gastric secretions—one of the most common clinical causes of ARDS. Lung injury occurs rapidly, especially to the epithelium. The injury is probably related, in part, to the low pH of the aspirated stomach contents. Aspirated acid is almost immediately neutralized. However, within hours, proinflammatory mediators are released, the injured lung is infiltrated with neutrophils, fibrin accumulates in the alveolar spaces, and further structural damage is seen on histologic examination. Thus, even direct toxic injuries damage the lung in part through activation of inflammatory pathways.

■ Biologic Markers

Considerable interest exists in finding a simple test of blood, urine, or BAL fluid that would identify patients at risk for, or in the earliest stages of, ARDS, or that might predict clinical outcome.

Although products of complement activation have been proposed as markers, their serum levels correlate poorly with lung injury. Measurement of circulating endotoxin is not appropriately sensitive or specific for the presence or risk of developing lung injury. The same is true for measurements of release or activity of angiotensin-converting enzyme.[36] von Willebrand factor (VWF) antigen may be useful as a plasma marker of impending ARDS in patients with nonpulmonary sepsis.[37] VWF levels are elevated in the edema fluid and plasma of patients with ARDS and correlate with poor clinical outcomes.[38] Also, work has indicated that elevated levels of plasma angiopoietin 2 predict the development of ALI in patients with sepsis identified in the emergency department.[39] While increases in other biochemical and inflammatory markers, including surfactant protein D and IL-6, correlate somewhat with lung injury and mortality, no simple biologic marker currently serves in the same diagnostic capacity, as do cardiac enzymes in evaluation of suspected acute myocardial infarction.[40]

Other mediators of inflammation in ARDS have been studied. For example, increased levels of TNF are detected in blood and BAL fluid in lung injury, but an association between TNF levels and the development of ARDS has not been found.

Furthermore, elevated TNF levels are found in patients with severe congestive heart failure. Lipoxygenase products of arachidonic acid metabolism have been detected in pulmonary edema fluid, BAL fluid, plasma, and urine, and elastase has been detected in BAL fluid in the setting of lung injury.

ARDS follows a wide variety of insults of varying severity. In a study of injured patients with ARDS, investigators found increased levels of IL-6 and thrombomodulin in those who had fewer ventilator-free days.[41] However, since ARDS is such a heterogeneous disorder, with so many possible mechanisms, it is unlikely that any single marker that unequivocally identifies the risk or the presence of ARDS will be found. An investigative focus on particular subgroups of patients with common causes of lung injury, coupled with study of much larger groups of more precisely diagnosed patients, may be a better pathway for future research.

Figure 140-2 depicts multiple pathways involved in the pathogenesis of ARDS in the context of normal and injured alveoli. The depictions place emphasis on potential pathways for injury across the vascular endothelium and alveolar epithelium.

VENTILATOR-INDUCED LUNG INJURY

The most important development of the last 10 years in our understanding of the pathogenesis and treatment of ARDS is recognition that the long-standing practice of mechanically ventilating affected patients using high tidal volumes and airway pressures worsens the injury. Animal studies first suggested the potential contributory role of high tidal volumes and elevated airway pressures in the pathogenesis of lung injury; subsequently, clinical trials confirmed the findings.[4]

■ Animal Studies

Experimental studies have shown that ventilation using high tidal volumes may increase vascular filtration pressures; produce stress fractures of microvascular endothelium, alveolar epithelium, and basement membranes; and cause lung rupture (so-called ventilation-induced lung injury).[42] The injury appears to be due to increased lung excursions at high volumes (volutrauma), rather than the high-airway pressure, per se, since it can be prevented by limiting thoracic motion (e.g., by placing the chest in a cast).

The concept of volutrauma was first established in 1974 when investigators found that modestly elevated tidal volumes, especially in the absence of PEEP, caused lung edema in rats.[43] Several years later, additional animal studies further demonstrated the potential

FIGURE 140-2 Multiple cellular responses and mediators contribute to alveolar-capillary membrane injury *(right-hand side)* and the transition from normal alveolar structure and function *(left-hand side)* in the acute phase of ALI/ARDS. Original investigations of the pathogenesis of ALI/ARDS searched for single mediators that provided final common pathways to inflammation and alveolar edema. Current concepts of pathogenesis involve multiple molecular factors of several classes, a variety of responding cells, and an imbalance between injurious and reparative signals and pathways. See text and Ware & Matthay (2000). *(Reproduced with permission from Ware LB, Matthay MA. The acute respiratory distress syndrome. N Engl J Med. 2000;342(18):1334–1349.)*

injurious role of high tidal volumes and elevated airway pressures, an effect termed *ventilator-induced lung injury* (VILI).[44] Subsequent experiments demonstrated that VILI could also induce release of several proinflammatory cytokines, injuring the lung and other organs—a process referred to as "biotrauma."[45] These animal studies stimulated clinical investigation that revolutionized the care of patients with ARDS.[44]

■ Clinical Studies

The compelling evidence from animal experiments and small clinical trials prompted clinical studies aimed at testing the potential benefit of lower tidal volumes and reduced airway pressures during mechanical ventilation in management of ARDS. In a large, multicenter, National Heart, Lung, and Blood Institute–sponsored trial of 861 patients, mortality was reduced from 40% to 31% using a tidal volume of 6 mL/kg of ideal body weight and a limited plateau airway pressure of less than 30 cm H_2O.[46] In this trial, use of small tidal volumes was associated with a lower incidence of nonpulmonary organ failure. The protocol for carrying out the lung protective ventilatory strategy is described in detail in Table 140-1. The results of the trial transformed the management of patients with ARDS. Notably, a follow-up clinical trial demonstrated that ventilation using the limited tidal volumes and plateau pressure of the original study is associated with an overall reduction of mortality to 26%. In the follow-up trial, although elevated levels of PEEP did not decrease mortality, the basic lung protective strategy was validated as effective.

The beneficial mechanism underlying the low tidal volume strategy has been well studied. An Italian study reported that use of low tidal volumes in patients with ARDS attenuates the inflammatory response in both lungs and bloodstream, as measured by reductions

in neutrophil and cytokine concentrations in BAL and cytokines in circulating blood.[47] Other studies have confirmed a number of these findings. In addition, a reduction in alveolar epithelial injury appears likely, based on a decline in plasma surfactant protein D levels. Additional clinical and experimental studies are underway. A reduction in lung endothelial and epithelial injury, attenuated inflammatory responses, reduced edema formation, and more rapid resolution of lung edema are likely part of the mechanism(s).[4] Figure 140-3 summarizes current knowledge of the mechanisms of VILI.

There has not been an accurate method to estimate the extent of pulmonary edema in a patient with ARDS. However, the Radiographic Assessment of Lung Edema (RALE) score is a simple, noninvasive way to assess the extent and density of alveolar opacities on the chest radiograph, using a scoring system based on the density and extent of infiltrates in each of the four quadrants on the chest radiograph.[48] An earlier version of the RALE score correlated with direct gravimetric assessment of pulmonary edema in donor lungs.[48] In addition, higher RALE scores identified patients with higher mortality in a subset of patients in the FACTT trial. In addition, patients who were treated with a conservative fluid therapy had a significantly reduced RALE score compared with those treated with a fluid-liberal strategy.

■ Resolution of Acute Lung Injury

In the last three decades, notable progress has occurred in elucidating the mechanisms responsible for resolution of lung edema.[49] More limited progress characterizes our understanding of the resolution of lung inflammation.

Considerable advances have been made in our understanding of the clearance of fluid and solute from alveoli. Edema can be cleared via five routes: lymphatics, airways, blood vessels, the pleural space, and the mediastinum. Active sodium and chloride transport across the alveolar and distal airway epithelial barriers into the interstitium drives edema fluid removal from the airspaces.[50] The uninjured alveolar epithelium has a remarkable ability to rapidly clear fluid from the airspaces. Even when mild to moderate alveolar injury occurs, salt and water transport capacity is often preserved. In severe injury, when the barrier is disrupted, the capacity to clear edema is lost. The vascular endothelium becomes the limiting barrier between the vascular space and airspace. Clinically, the capacity to remove some alveolar edema fluid in the first 4 to 12 h following ARDS is a favorable prognostic finding; the associated mortality rate is only 20%. In contrast, an inability to resorb alveolar edema fluid early in the course of injury is associated with a mortality of nearly 80%. Thus, the function of the alveolar epithelial barrier early in the course of ARDS may be a useful prognostic index, serving as a marker of the severity and extent of injury.[51]

Resolution of ARDS requires effective: (1) reabsorption of alveolar edema, (2) repair of the epithelial and endothelial barriers, and (3) removal of inflammatory cells and exudates from the distal airspaces. Reabsorption of alveolar edema occurs through vectorial transport of sodium and chloride across alveolar epithelial type I and II cells to create a mini-osmotic gradient to reabsorb water.[52–54] This process is impaired in ARDS, in part because of apoptosis and necrosis of alveolar epithelium and defects in transcellular ion transport induced by proinflammatory cytokines, oxidants, and hypoxia.[29,52,55–58]

In uninjured, ex vivo human lungs, alveolar fluid clearance (AFC) is increased by administration of the β2 agonist salmeterol.[59] However, the β-adrenergic-mediated effect by augmentation of intracellular cAMP works primarily when the alveolar epithelium is not injured, as in hydrostatic edema. Aerosolized or intravenous β2 agonist therapy does not appear to improve clinical outcomes.[60,61]

Clearance of protein from flooded alveoli is much slower (1%–2% per hour) than clearance of fluid (10%–20% per hour), resulting in an increased concentration of protein in the airspaces. If alveolar edema formed during increased lung vascular permeability clots, its removal from flooded alveoli may be slowed. Clotting may occur because extravasation of plasma into airspaces may lead to clotting system activation by surfactant or macrophage-derived procoagulants.

Most of the interstitial water in pulmonary edema lies in the peribronchovascular loose connective-tissue spaces, rather than in alveolar walls. Because the lymphatic capillaries are arranged to drain only the alveolar wall interstitium, this route for edema removal is not significant for most interstitial edema. Some fluid from the loose peribronchovascular interstitium may drain directly into the bloodstream by crossing the walls of blood vessels in the lungs. Edema may also drain into the pleural space.

Pleural effusions are more common in increased pressure pulmonary edema (25%–50% of patients; if unilateral, usually on the right). However, pleural effusions occur in ARDS as well (35% of patients). As much as 25% to 30% of edema fluid may leave the lungs through the pleural space. A significant portion of interstitial

FIGURE 140-3 Mechanisms of ventilator-associated lung injury (VALI). **A**. Acute lung injury leads to lung endothelial and epithelial injury, increased permeability of the alveolar-capillary barrier, flooding of the airspace with protein-rich pulmonary edema fluid, activation of alveolar macrophages with release of proinflammatory chemokines and cytokines, neutrophil margination and activation, and fibrin deposition (hyaline membranes). **B**. If the injured lung is ventilated with high tidal volumes and high inflation pressures (high-stretch ventilation), then lung injury is exacerbated, with increased lung endothelial and epithelial injury and/or necrosis, enhanced neutrophil margination, release of injurious neutrophil products such as proteases and oxidants, increased release of proinflammatory cytokines from alveolar macrophages and the lung epithelium, increased fibrin deposition, and increased hyaline membrane formation. Injurious mechanical ventilation can also impair alveolar fluid clearance (AFC) mechanisms. **C**. In contrast, a protective ventilatory strategy (low-stretch ventilation) can limit further lung endothelial and epithelial injury, reduce the release of proinflammatory cytokines, and enhance AFC through the active transport of sodium and chloride across the alveolar epithelium, thereby reducing the quantity of pulmonary edema and allowing endothelial and epithelial repair to occur. Epithelial repair occurs through migration, proliferation, and differentiation of alveolar epithelial type II cells to repopulate the denuded basement membrane. *(Reproduced with permission from Matthay MA, Ware LB, Zimmerman GA. The acute respiratory distress syndrome. J Clin Invest. 2012;122(8):2731–2740.)*

edema probably follows the prevailing pressure gradient in the lungs to drain into the mediastinum, where it may be picked up by the lymphatics.

Short-term alveolar protein clearance appears to proceed primarily by paracellular diffusion. The process depends on the size of the proteins. Most proteins are cleared intact, rather than as degraded, smaller fragments. However, a few specific proteins (e.g., vasoactive intestinal peptide and gastrin) are degraded before being cleared.

Finally, the general consensus is that transcytosis (transport via vesicles) is not a major mechanism for clearing bulk quantities of albumin or other proteins from the alveolar space. Over the long term, phagocytosis and catabolism by macrophages account for most protein clearance from the alveolar spaces. All insoluble, precipitated proteins are removed in this way. Macrophages are also ultimately responsible for removing senescent and dead neutrophils and other debris. The presence of a small, ciliated surface area of the distal airspaces suggests that the mucociliary route accounts for only a minor fraction of alveolar protein clearance. Complete clearance of alveolar protein from pulmonary edema by any route is slow.

AFC appears to be clinically important. In a study of 116 patients with ARDS, the rate of AFC in patients with shock was significantly slower than in those without shock. AFC also decreased significantly as the number of vasopressors required increased. The findings suggest that vasopressor use may be a marker for impaired alveolar epithelial barrier integrity in patients with ARDS and shock.[62]

E-CIGARETTE AND VAPING-ASSOCIATED LUNG INJURY

Early in 2020, the CDC reported 2558 cases in the United States of patients hospitalized due to e-cigarette and vaping associated lung injury (EVALI), along with 60 fatalities. All of these cases of acute lung injury in young adults had one common finding: use of electronic cigarette products.[63]

The diagnosis of EVALI requires reported use of e-cigarette or vaping products within 3 months of symptom onset, compatible chest imaging findings, and an evaluation that excludes infectious etiologies. Although the etiologic agents initially were unclear, as cases mounted, tetrahydrocannabinol (THC) products in electronic devices were implicated, including many from black market sources. Furthermore, discovery that vitamin E acetate (VEA) is used in the extraction of THC liquid, and is an additive in THC-containing products, led to further research of this substance as the primary causative agent. The largest study of 82 patients that incorporated use of bronchoalveolar lavage (BAL) showed that 94% had VEA in the BAL fluid compared to none in healthy controls.[64]

Finally, a study in laboratory mice using cell cultures demonstrated that aerosolized VEA causes dose-dependent pulmonary edema, increased alveolar–capillary barrier permeability to protein, and a bronchiolocentric pattern of inflammation, including lipid-laden and multinucleated macrophages. The investigators also showed that VEA aerosol causes direct injury to alveolar type II cells, including secretion of inflammatory cytokines.[65]

SARS-COV2 ARDS

The SARS-CoV2 pandemic has accelerated ARDS research, providing insight into COVID-19–related lung injury. A large, systematic, multicenter study has demonstrated that patients with COVID-19–related ARDS have lung morphology and respiratory mechanics that largely match those of classic ARDS.[66] In both types of ARDS, there is marked upregulation of proinflammatory biomarkers, an increase in capillary endothelial permeability, and an increase in inflammatory cells (neutrophils, monocytes/macrophages) in the vascular and alveolar compartments.[67] Furthermore, previously identified hyperinflammatory and hypoinflammatory phenotypes have been prospectively validated in COVID-19–related ARDS.[68] However, significantly fewer hyperinflammatory phenotypes have been identified than in other etiologies of ARDS. This is surprising, given that the term *cytokine storm* is often used to describe COVID-19–related ARDS. While many authors have used the term in describing the hyperinflammatory response in COVID-19, median IL-6 levels in patients with the hyperinflammatory phenotype of non–COVID-related ARDS are 10- to 200-fold higher than levels in patients with severe COVID-19.[69] These studies demonstrate that COVID-19–related ARDS is a heterogenous entity that is similar to ARDS due to other etiologies, including both epithelial and endothelial damage. Treatment should follow evidence-based guidelines.[70]

Immunophenotyping of neutrophils, lymphocytes, and monocytes has demonstrated that in BAL the neutrophil-to-lymphocyte ratio, especially in the context of a reduction in CD8+ T cells, is a marker of COVID-19–related disease severity. Interferons play an important role in early host defense, and several studies suggest impaired interferon response in some patients with COVID-19–related injury who develop severe disease.[71]

Relative to milder forms of COVID-19–related ARDS, significant alterations in severe COVID-19–related ARDS include (1) a higher SARS-CoV-2 viral load in both the upper airways (nasal lumen) and in the circulation, (2) a higher neutrophil count and activity (i.e., neutrophil extracellular trap [NET] formation), (3) an increase in inflammatory biomarkers and thrombosis, (4) greater monocyte HLA-DR expression and lymphocyte activation (CD8+ T cell CD38 expression), and (5) more damage to the alveolar–interstitial–capillary unit. Neutrophils produce NETS through a cell death process called NETosis. Extracellular chromatin and histones are released upon stimulation from pathogens, such as viruses. NETS trap and kill pathogens, but upon dysregulation, they may lead to tissue damage and thrombosis.[72]

Vascular injury and thromboses of pulmonary capillaries, as well as small and even larger pulmonary vessels, are more common COVID-19–related ARDS.[73] Additionally, evidence has arisen that patients with severe COVID-19–related ARDS have higher pulmonary dead space, decreased lung perfusion, and elevated D-dimer levels.[74] Several candidate pathways may account for lung and systemic vascular injury, including neutrophil extracellular traps and hyperfibrinolysis that contributes to the elevated D-dimer levels. A pathologic study comparing COVID-19–related ARDS with other causes of ARDS demonstrated nine times more alveolar capillary thrombi in COVID-19–related cases than in historic autopsies from patients with influenza-induced ARDS.

Treatment for COVID-19–related ARDS (Chapter 141) should follow well-established, evidence-based guidelines. While use of steroids in the treatment of ARDS has been controversial for the past four decades, the large UK RECOVERY trial showed a mortality benefit of dexamethasone in hospitalized patients with COVID-19 who require supplemental oxygen or mechanical ventilation.[75] Although there are still many open questions about trial design,[76] these findings support those in another recent non-COVID trial. In a Spanish, open-label, randomized, multicenter trial of 277 patients with moderate to severe non–COVID-19–related ARDS, a 15% absolute reduction in 60-day mortality (36% to 21%; $p = 0.0047$) in dexamethasone-treated patients was observed.[77]

Finally, ongoing trials are addressing use of monoclonal antibodies, low-dose versus full-dose anticoagulation, and mesenchymal stem cells.

CONCLUSIONS

Among the major advances in respiratory medicine and physiology over the last three decades has been the acquisition of important new knowledge on the physiology of fluid, solute, and protein transport in healthy and diseased lungs. Pulmonary edema, defined as the abnormal accumulation of extravascular lung fluid, is a pathologic state that occurs when fluid is filtered into the lungs faster than it can be removed.

The many causes of pulmonary edema are grouped into two main pathophysiologic categories: (1) increased pressure edema, which results from an increase in hydrostatic or protein osmotic forces (or both) that act across the barriers that normally restrict movement of fluid and solutes in the lungs; and (2) increased permeability edema, which is seen in ARDS, and in which a breakdown of the normal barrier properties of lung endothelium or epithelium develops. Although these two different types of pulmonary edema share many features, usually they can be distinguished by careful clinical, radiologic, and physiologic evaluation. They also differ in treatment and prognosis.

Major advances in the treatment of ARDS have occurred because of the successful application of lung protective ventilatory strategies early in the course of the illness (Table 140-1). Use of a low tidal volume (6 mL/kg of ideal body weight), coupled with a plateau pressure limit (<30 cm H_2O) has resulted in the first therapy demonstrated to reduce mortality in patients with ARDS.[46]

Another major advance in the treatment of ARDS was triggered by findings from the Fluid and Catheter Treatment Trial (FACTT), a large randomized trial comparing liberal and conservative fluid management strategies in affected patients.[10] A marked difference in outcome was reported, with patients in the conservative fluid management arm having 2.5 more ventilator-free days (and improved physiology) than those in the liberal fluid management arm. In addition, although not statistically significant, a 2.9% reduction in the 60-day mortality rate was noted in the conservative fluid management arm. Patients were also randomized to receive either a pulmonary arterial catheter or a central venous catheter for monitoring and fluid management. No differences were noted in clinical outcomes between the two groups.[77]

New insights into the pathogenesis of ARDS suggest that other therapies may also prove efficacious in reducing mortality in this common form of severe acute respiratory failure. A major development has been the ability to conduct large, prospective, randomized clinical trials (e.g., those sponsored by the National Heart, Lung, and Blood Institute) to test a variety of therapies important in supportive patient care, including use of mechanical ventilation, intravenous fluids, and a variety of pharmacologic agents.

Interest exists in the possibility that cell-based therapy using bone marrow–derived mesenchymal stem cells may be effective for more severe ARDS.[4,78] Such trials have led to a better understanding of the pathogenesis of human ARDS and have confirmed the importance of VILI. In addition, ancillary pathogenetic studies carried out on biologic samples from clinical trials have advanced our understanding of underlying mechanisms, especially leading to a new era potentially to subphenotype ARDS patients based on plasma biologic markers and selected clinical data. In the future, clinical studies will be needed to test new therapeutic strategies suggested by basic investigation conducted in animal models of ALI, including efforts to treat patients at an early phase of acute respiratory failure, prior to the need for positive pressure ventilation.[4,79]

CHAPTER 141

Acute Respiratory Distress Syndrome: Clinical Features, Management, and Outcomes

John P. Reilly
Jason D. Christie

DESCRIPTION AND DEFINITIONS

In 1967, Ashbaugh et al.[1] described a syndrome characterized by the acute onset of dyspnea, severe hypoxemia, diffuse lung infiltrates, and decreased respiratory system compliance in the absence of evidence for congestive heart failure (CHF). The syndrome, initially called acute respiratory distress in adults (to contrast it with acute respiratory distress in neonates), is now known as the acute respiratory distress syndrome (ARDS). Following the initial report, other authors utilized various definitions that incorporated elements related to time of onset, presence of hypoxemia and radiographic infiltrates, and absence of overt CHF.

In 1988, Murray and others introduced the Lung Injury Score (LIS), an assessment tool for ARDS that reflects the extent of radiographic infiltrates, severity of hypoxemia and reduced respiratory system compliance, and level of positive end-expiratory pressure (PEEP) used in mechanically ventilating affected patients.[2] The LIS incorporates four parameters that are graded on a scale of 0 to 4: (1) ratio of Pa_{O_2} to FI_{O_2} (Pa_{O_2}/FI_{O_2}); (2) total respiratory compliance; (3) level of PEEP; and (4) extent of radiographic infiltrates (assessed by noting the number of quadrants in the chest radiograph demonstrating infiltrates). The LIS equals the sum of the scores for the four variables divided by 4. In clinical studies, a score of 2.5 or more was generally used as a threshold for severe disease.

Consensus Definitions of Acute Lung Injury and ARDS

Prior to 1994, published studies used nonuniform definitions of ARDS, prompting an American European Consensus Conference (AECC) to develop standardized definitions for ARDS and acute lung injury (ALI)—a broader category that encompassed ARDS.[3] The AECC definitions included the acute onset of illness, bilateral chest radiographic infiltrates consistent with pulmonary edema, poor systemic oxygenation, and absence of evidence for left atrial hypertension (Table 141-1A). The syndrome was referred to as ALI when the ratio of Pa_{O_2} to FI_{O_2} (Pa_{O_2}/FI_{O_2}) was ≤ 300, and ARDS when the ratio was ≤ 200. The AECC definitions of ALI and ARDS were intentionally broad in order to encompass different types of acute hypoxemic respiratory failure occurring in a wide variety of settings.

Development of the Berlin Definition of ARDS

The standardization of definitions of ALI and ARDS led to significant advances in the understanding of the syndrome and allowed researchers and clinicians to communicate findings using common criteria. The AECC definitions were widely used in clinical trials, including those that demonstrated therapeutic benefit.[4,5] In addition, they added important validity to the definition, allowing clinicians to generalize trial results to clinical decisions involving their own patients. Despite this standardization, few data were available to support the reliability and validity of ARDS definitions. In fact, several components of the AECC definition have been recognized as problematic: (1) Acute onset is not defined within a specific time frame. (2) The chest radiograph is subject to variability in interpretation.[6,7] (3) Pa_{O_2}/FI_{O_2} may vary according to ventilator parameters, for example, PEEP, and at extremes of FI_{O_2}. (4) Accuracy in excluding the presence of heart failure may be influenced by measurement methodology and timing, as discussed below.[8]

Given these limitations, an international expert panel was convened in Berlin in 2012 to revise the definition of ARDS. The resultant "Berlin definition" of ARDS addresses ambiguities in the prior AECC definition. The authors of the Berlin definition also applied proposed criteria for the syndrome to existing databases of patients with ARDS to specifically address the predictive validity of a new ARDS definition.[9] According to the Berlin definition, ARDS is defined as a syndrome characterized by (1) onset within 1 week of a known clinical insult, (2) bilateral radiographic opacities not fully explained by pleural effusions, atelectasis, or nodules, (3) respiratory failure not fully explained by cardiac failure or fluid overload, and (4) poor systemic oxygenation, with a $Pa_{O_2}/FI_{O_2} \leq 300$ and a PEEP or CPAP ≥ 5 cm H_2O. The definition also categorizes syndrome severity as mild, moderate, or severe, based on Pa_{O_2}/FI_{O_2}. According to the Berlin definition, patients who previously were diagnosed with ALI, but not ARDS (i.e., $Pa_{O_2}/FI_{O_2} \leq 300$, but >200), are referred to as having mild ARDS, with ALI now an obsolete term. Moderate ARDS is defined as $Pa_{O_2}/FI_{O_2} \leq 200$, but >100, and severe ARDS is defined as $Pa_{O_2}/FI_{O_2} \leq 100$ (Table 141-1B).

While the Berlin definition leaves the AECC definition of ARDS largely unchanged, the new definition addresses several specific ambiguities of the prior diagnostic criteria. First, the definition

TABLE 141-1A American European Consensus Conference Criteria for Acute Lung Injury (ALI) and the Acute Respiratory Distress Syndrome (ARDS)

Clinical Variable	Acute Lung Injury	Acute Respiratory Distress Syndrome
Onset	Acute	Acute
Hypoxemia	$Pa_{O_2}/FI_{O_2} \leq 300$ mm Hg	$Pa_{O_2}/FI_{O_2} \leq 200$ mm Hg
Chest radiograph	Bilateral infiltrates consistent with pulmonary edema	Bilateral infiltrates consistent with pulmonary edema
Noncardiac etiology	No clinical evidence of left atrial hypertension or, if measured, pulmonary artery wedge pressure ≤ 18 mm Hg	No clinical evidence of left atrial hypertension or, if measured, pulmonary artery wedge pressure ≤ 18 mm Hg

TABLE 141-1B Berlin Definition of Mild, Moderate, and Severe Acute Respiratory Distress Syndrome (ARDS)

Clinical Variable	Mild ARDS	Moderate ARDS	Severe ARDS
Onset	Onset within 1 week of clinical insult known to result in ARDS		
Hypoxemia	$Pa_{O_2}/FI_{O_2} \leq 300$ mm Hg PEEP or CPAP ≥ 5 cm H_2O	$Pa_{O_2}/FI_{O_2} \leq 200$ mm Hg PEEP ≥ 5 cm H_2O	$Pa_{O_2}/FI_{O_2} \leq 100$ mm Hg PEEP ≥ 5 cm H_2O
Chest radiograph	Bilateral opacities, not explained by effusions, atelectasis, or nodules		
Noncardiac etiology	Respiratory failure, not fully explained by cardiogenic pulmonary edema; exclude hydrostatic edema if no clinical risk factor present		

Data from ARDS Definition Task Force, Ranieri VM, Rubenfeld GD, et al. Acute respiratory distress syndrome: the Berlin Definition. JAMA. 2012;307(23):2526–2533.

defines “acute onset” and attempts to clarify chest radiograph criteria. In addition, the Pa_{O_2}/FI_{O_2} criterion is influenced by the level of PEEP and other transient factors, including the presence or absence of airway secretions or inadequate sedation. Increasing PEEP generally increases Pa_{O_2} at a given FI_{O_2}. The consequent increase in Pa_{O_2}/FI_{O_2} may result in a value that no longer meets criteria for ARDS. Conversely, without any PEEP, values of $Pa_{O_2}/FI_{O_2} < 300$ may reflect simple atelectasis, rather than ARDS. Adding PEEP may recruit sufficient atelectatic lung to raise $Pa_{O_2}/FI_{O_2} > 300$, thereby excluding such patients from meeting this criterion for ARDS. The Berlin definition addresses this concern directly by requiring a minimum level of PEEP when a determination of Pa_{O_2}/FI_{O_2} ratio is made.

Finally, given the declining use of pulmonary artery catheters (PACs),[10] potential inaccuracies of pulmonary artery occlusion pressure (PAOP) measurements, and the now recognized possibility of concomitant hydrostatic edema and ARDS, the Berlin definition no longer specifies PAOP requirements.[11,12] PAOP in ARDS may be higher than 18 mm Hg due to intravascular volume loading. Conversely, some patients with pulmonary edema due to CHF and high left atrial pressures have a normal PAOP by the time the catheter is inserted and PAOP is measured. The Berlin definition specifies that the respiratory failure of ARDS is not fully explained by cardiac failure or fluid overload and requires objective assessment to exclude hydrostatic edema (e.g., an echocardiogram) if no risk factor for ARDS is present.

The predictive validity of the Berlin ARDS definition was assessed in several large cohorts of patients with ALI, as defined by AECC. Compared with the AECC definition, the Berlin definition had marginally better predictive validity for mortality. The identified categories of mild, moderate, and severe ARDS corresponded with progressive increases in mortality. Proposed ancillary variables in the definition of severe ARDS, including a chest radiograph with three or four quadrants demonstrating opacities, PEEP ≥ 10 cm H_2O, and either a respiratory system static compliance ≤ 40 mL/cm H_2O or a corrected expired volume per minute of at least 10 L/min did not improve the predictive validity of the definition of severe ARDS. Therefore, the final definition did not include any of these ancillary variables.

While the Berlin definition has been accepted by major professional organizations, it is important to note that many of the studies referred to in this chapter were performed prior to its development and, therefore, utilize the older AECC definition of ALI and ARDS. Additionally, problems remain in consistently identifying ARDS including interobserver variability in chest radiograph interpretation and continued challenges in distinguishing cardiogenic from noncardiogenic edema.[13,14] The Berlin criteria are also difficult to use in resource-limited settings, potentially resulting in ARDS under recognition in much of the world. The proposed Kigali modification of the Berlin criteria attempts to overcome this limitation by allowing for ARDS to be diagnosed in the absence of chest radiography, mechanical ventilation, and/or blood gas measurements.[15] Further refinements in the reliability and validity of definitions of ARDS constitute important future directions for clinical studies, and may potentially be improved by the integration of new technologies, such as lung ultrasound or measurements of extravascular lung water,[16,17] as well as molecular markers reflecting the underlying biology of ARDS.[18] In addition, attempts at understanding the heterogeneity underlying the syndrome may allow for identification of ARDS subgroups with potential diverse risk factors and pathogenesis. More reliable definitions will not only improve estimates of the public health impact of these syndromes, but also will decrease misclassification errors, which can be especially problematic for research aimed at clarifying underlying mechanisms.

EPIDEMIOLOGY

Over the last several decades, the epidemiology of ARDS has become more clearly delineated.

■ Incidence and Mortality Rate

A landmark epidemiologic study of the incidence of ARDS in the United States between 1999 and 2000—the King County Lung Injury Project (conducted in King County, Washington)—represents the first broad, population-based epidemiologic study of ARDS in the United States using the standardized AECC definitions.[19] Study results included an estimated incidence of ARDS based on a $Pa_{O_2}/FI_{O_2} \leq 300$ of 78.9 per 100,000 person-years and an age-adjusted incidence of 86.2 per 100,000 person-years. The incidence of what is now called moderate or severe ARDS was estimated as 58.7 per 100,000 person-years, with an age-adjusted incidence of 64.0 per 100,000 person-years. The incidence of ARDS increased dramatically with age, with an incidence of 306 per 100,000 person-years for ages 75 through 84 years. By extrapolation, an estimated 190,600 cases of ARDS occur each year in the United States (Table 141-2).

Although prior estimates of the incidence of ARDS had been lower, the studies were limited by incomplete and nonvalidated data, inaccuracies in the definition of the syndrome, and use of administrative coding.[19–25] Thus, the estimates from King County Lung Injury Project serve as the best indicator of the public health impact of ARDS in the United States. Additionally, the incidence of ARDS over time may be decreasing. In a retrospective cohort study of all patients admitted to the ICU at the Mayo Clinic from 2001 to 2008, the incidence of ARDS declined significantly during the period of observation.[26] Since the Mayo Clinic provides all ICU-level care to the population of Olmsted County, Minnesota, the authors could estimate the incidence trends of ARDS over time. The age and sex

TABLE 141-2 Estimated Incidence, Hospital Days and Intensive Care Unit (ICU) Days for Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS) in the United States Based on American European Consensus Criteria for ALI and ARDS

Variable	ALI	ARDS
Crude incidence, per 100,000 person-years	78.9	58.7
Age-adjusted incidence, per 100,000 person-years	86.2	64.0
Estimated annual number of cases in United States	190,600	141,500
Estimated annual number of hospital days in United States	3,622,00	2,746,000
Estimated annual number of days in ICU in United States	2,154,000	1,642,000

adjusted incidence of moderate and severe ARDS ($\text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2} \leq 200$) declined from 81 cases per 100,000 person-years in 2001 to 38.3 cases per 100,000 person years in 2008. This trend appeared to be driven by declining hospital-acquired ARDS, perhaps the result of improvements is overall ICU care and the increasing use of lower tidal volume ventilation (see "Approach to Treatment," below).

Previous reports of ARDS epidemiology utilized the AECC definition of ARDS and largely focused on a single country or region until the publication of The Large Observational Study to Understand the Global Impact of Severe Acute Respiratory Failure (LUNG SAFE).[27] The LUNG SAFE study was a multicenter, prospective cohort study of patients undergoing invasive and noninvasive ventilation conducted over 4 consecutive weeks of 2014 in 459 ICUs from 50 countries across 5 continents. The authors aimed to determine the ICU incidence of ARDS according to the Berlin definition, as well as, clinician recognition of ARDS and application of specific interventions. ARDS occurred in 10.4% of all ICU admissions and 23.4% of all patients requiring mechanical ventilation. The authors were unable to calculate the population incidence of ARDS because they could not estimate the population served by ICUs included in the study. The LUNG SAFE study also provided evidence that ARDS is under recognized as only 60% of ARDS cases identified by research were documented by treating clinicians.

During the time of observation in the King County Lung Injury Project study, the mortality from ARDS was 38.5%, translating into an estimated 74,500 annual deaths from ARDS in the United States.[19] Despite being conducted over a decade later, the LUNG SAFE study reported a similar hospital mortality of 40.0%.[27] Reported mortality estimates have ranged from 26% to 58%.[24–30] To put these figures into perspective, more people die annually with ARDS than from AIDS, asthma, and breast cancer combined.[31] Other than lung cancer, ARDS leads to more annual deaths than any type of cancer, including lymphoma, leukemia, and breast, prostate, colon, ovarian, and pancreatic cancers (Table 141-3). The most common causes of death among patients with ARDS arise from the underlying insult or subsequent nosocomial pneumonia and sepsis.[32,33] Only rarely do patients die from progressive hypoxia and respiratory failure.

TABLE 141-3 Estimated Annual Number of Deaths in the United States from Selected Causes

Cause	Number of Deaths
ARDS	59,000
Asthma	3311
HIV/AIDS	7638
Breast cancer	41,271
Leukemia	22,982
Lung cancer	156,614
Lymphoma	21,393
Ovarian cancer	14,312
Pancreatic cancer	37,371
Prostate cancer	27,929

Data for ARDS from Rubenfeld GD, Caldwell E, Peabody E, et al. Incidence and outcomes of acute lung injury. N Engl J Med. 2005;353(16):1685–1693; all other are from CDC National Center for Health Statistics estimated number of deaths in 2011.

Several studies have suggested that ARDS mortality has decreased over time.[33–36] In one hospital using the same definition of ARDS throughout the period analyzed, the mortality rate was 68% in 1982, 29% in 1996, and in the mid-30% range in 1997 and 1998.[32] Obviously, the decrease cannot be ascribed to widespread application of low tidal volume ventilation strategies, since the decline was observed prior to publication of the study reporting the value of using a "low stretch" ventilator protocol in 2000.[4] The improvement is likely attributable to enhancements in general ICU care, including prevention of nosocomial pneumonias and other infections, earlier institution of enteral nutrition, routine use of stress ulcer prophylaxis, and improved teamwork in the ICU.

Interestingly, the case fatality rate for patients with ARDS due to sepsis remained the same over the same time frame noted earlier, while that for patients with ARDS due to trauma or other causes decreased significantly. Mortality rates among subjects enrolled in ARDS Network trials[4,37–40] appear to have decreased from 35% (1996–1997) to 26% (2004–2005).[34,41] These findings were robust in adjusting for covariates, including severity of illness and use of low tidal volume ventilation. However, these rates were obtained from clinical trials in specialized centers, excluding large numbers of patients with high-risk comorbidities. Recent systematic reviews of clinical trials and more inclusive prospective cohort studies have drawn opposing conclusions.[35,42] Also, the previously noted study from the Mayo Clinic demonstrated a reduction in ARDS incidence, but it failed to show a change in mortality.[26] While it is unclear whether or not survival from ARDS is improving, the mortality rate remains unacceptably high and represents a major public health problem. Furthermore, as the population of the United States becomes older, the incidence of those at risk for ARDS and ARDS-related death can be expected to rise.

■ Precipitating Causes

The severe, extensive lung inflammation characteristic of ARDS represents the common final pathogenic process in response to a large variety of precipitating causes,[43–46] resulting in either direct or indirect (systemic) lung injury.[47,48] In general, *direct* causes of ARDS include those that originate within the lung, such as aspiration of gastric contents or viral pneumonia. Examples of *indirect* causes include sepsis, ingested toxins, hypotension, and ischemia–reperfusion injury. Although some causes of ARDS may fit into either

TABLE 141-4 Common Direct and Indirect (Systemic) Precipitating Causes of ARDS

Direct Precipitating Causes	Indirect (Systemic) Precipitating Causes[a]
Aspiration of gastric fluids	Acute pancreatitis
Bacterial pneumonia (diffuse), e.g., Legionnaires' disease	Blood transfusions with transfusion-related acute lung injury (TRALI)
Chest trauma with lung contusion	Post–cardiopulmonary bypass
Near drowning	Primary graft failure of lung transplantation
Pneumonia due to *Pneumocystis carinii*	Severe sepsis and septic shock
Toxic inhalations, e.g., smoke inhalation, inhaled crack cocaine	Toxic ingestions, e.g., aspirin, tricyclic antidepressants
Viral pneumonia, e.g., influenza, severe acute respiratory syndrome (SARS)	Trauma with multiple fractures and the fat-emboli syndrome

[a] *In indirect or systemic mechanism of lung injury, the lung injury results from deleterious effects on the alveolar epithelium by inflammatory or other mediators delivered via the pulmonary circulation.*

category (e.g., multilobar pneumonia with septic shock), this simple classification scheme is useful both for considering the many predisposing causes of ARDS and their varying mechanisms of lung injury and for future development of therapies aimed at different categories of ARDS. Table 141-4 lists precipitating causes of ARDS according to this construct.

■ Factors Influencing Risk of ARDS

Not all patients with an underlying cause of ARDS (e.g., sepsis) develop the syndrome. In addition to inherent risk differences within at-risk populations, specific clinical variables may be important.

Clinical variables found to be associated with an increased risk of ARDS include chronic alcohol abuse,[49] hypoproteinemia,[50] advanced age,[19] increased severity, and extent of injury or illness as measured by injury severity score (ISS) or APACHE score, transfusion of blood products,[45,51] cigarette smoking,[52,53] ABO histo-blood type A,[54,55] and ambient air pollution.[56,57] Diabetes mellitus and prehospitalization antiplatelet therapy appear to decrease the risk of ARDS.[58–60] The role of obesity in modifying ARDS risk is unclear, as excess soft tissue can render chest x-ray interpretation difficult; the potential role of obesity remains the subject of ongoing research. A higher body mass index has been associated with an increased incidence of ARDS; however, obesity has not been associated with a consistent change in mortality.[61–64] Since many studies of risk factors for ARDS have been retrospective or based on a single center's experience, the consistency and generalizability of identified risk factors have not been confirmed. Nonetheless, the mechanistic underpinnings and potential therapeutic implications of these probable associations are the subject of ongoing research.

In addition to clinical variables, several genetic variants have also been reported to influence ARDS risk.[65] Despite requiring a significant environmental insult such as sepsis or pneumonia, genetic heterogeneity resulting from evolutionary pressures likely contribute to the risk of developing ARDS. Initial studies based on a candidate gene approach identified functional variation in the gene encoding angiotensin-converting enzyme (*ACE*) and the surfactant protein B (*SFTPB*) gene, among many others, associated with ARDS risk.[66,67] More recently, larger scale genome-wide or near genome-wide approaches have identified variation in genes including *ANGPT2*, *PPFIA1*, *SELPLG*, and *FLT1* as associated with ARDS risk.[68–71] While many of the identified variants require further replication, the potential for genetics to impact our understanding and treatment of ARDS remains.

■ Factors Influencing Mortality from ARDS

Clinical variables at the onset of ARDS that are associated with increased mortality include advanced age, lower $\text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2}$, high plateau pressure (i.e., low respiratory system compliance),[72] greater extent of pulmonary infiltrates, sepsis, chronic liver disease, nonpulmonary organ dysfunction, increased global severity of illness, hypoproteinemia, and greater length of hospitalization prior to onset of ARDS.[19,50,72–77] In addition, an increased dead-space fraction has been identified as a risk factor for increased mortality, possibly indicating the importance of early loss of the pulmonary vascular bed as a sign of greater disease severity.[78,79] Although various precipitating causes of ARDS carry somewhat different prognoses, the strategy of low tidal volume ventilation utilized by the National Institutes of Health (NIH), National Heart, Lung, and Blood Institute (NHLBI)–sponsored ARDS Clinical Trials Network (ARDSNet) as part of its clinical trials appears to be equally efficacious in all subgroups.[4]

■ Predicting ARDS

Using the identified precipitating causes and modifying risk factors, investigators developed and validated a lung injury prediction score (LIPS) aimed at identifying those at highest risk of developing ARDS early.[80,81] The LIPS was developed in a multicenter cohort of 5584 hospitalized patients at risk for ARDS, among whom 7% eventually developed the syndrome. The LIPS is generated from the sum of points assigned for each of 6 predisposing conditions (shock, aspiration, sepsis, pneumonia, high-risk surgery, and high-risk trauma) and 9 risk modifiers (alcohol abuse, obesity, hypoalbuminemia, chemotherapy, need for oxygen, tachypnea, hypoxia, academia, and diabetes mellitus). The negative predictive value for a score <4 was 97%, while the sensitivity and specificity for ARDS of a score >4 were 69% and 78%, respectively. While not perfect, the LIPS allows for the identification of a higher-risk population and may prove useful for studies of preventative interventions. The LIPS-A study of aspirin to prevent ARDS utilized the LIPS to enroll patients at high risk of developing ARDS.[82] Although aspirin showed no benefit, the LIPS-A trial demonstrated the potential usefulness of an ARDS prediction tool and the goal to shift the syndrome's treatment paradigm to strategies aimed at prevention and treatment at the earliest phases of development.

■ ARDS Heterogeneity and Subtypes

The current clinical definition of ARDS is intentionally broad and encompasses patients with a marked degree of clinical, radiographic, pathologic, and biologic heterogeneity.[83] This heterogeneity is hypothesized to explain the inability to successfully translate promising preclinical therapeutics to critically ill patients. Subtypes of ARDS with unique clinical and biological features, as well as potentially heterogeneous treatment responses have increasingly been reported in the literature. Traditionally, ARDS subtypes have been distinguished based on the precipitating risk factor (e.g., sepsis, trauma) and direct/pulmonary versus indirect/extrapulmonary ARDS.[75,84,85] Direct lung injury precipitated by insults including pneumonia, aspiration, and pulmonary contusion is characterized by more radiographic heterogeneity, lower lung compliance, and potentially less response to PEEP.[86–89] Conversely, indirect lung injury precipitated by insults including nonpulmonary sepsis, nonthoracic trauma, and transfusion is characterized by radiographic homogeneity, higher lung compliance, and a higher likelihood of PEEP responsiveness. Biologically, direct ARDS is associated with higher plasma concentrations of biomarkers of epithelial injury, while indirect ARDS is associated with higher plasma concentrations of biomarkers of endothelial injury.[90] Other researchers have reported clinical heterogeneity based on timing of ARDS onset, severity of ARDS, and radiographic features of ARDS.[91–93]

More recently, unbiased approaches to identify endotypes (i.e., subtypes based on biology) of ARDS have been employed. Specifically, latent class analysis was applied to clinical and plasma biomarker data and identified two unobserved (latent) endotypes of ARDS within a heterogeneous population of ARDS patients enrolled in several ARDS Network Trials.[94–97] The first endotype was characterized by a hyperinflammatory phenotype and was associated with a higher mortality and worse shock compared to a second endotype without a hyperinflammatory response. Importantly, clinical features alone could not predict endotype classification. The authors also reported heterogeneous treatment effects based on PEEP strategy, fluid strategy, and statin therapy in a post-hoc analysis of ARDS clinical trials. Other investigators have applied clustering analysis techniques to observational ARDS cohorts and again identified reactive/hyperinflamed and uninflamed endotypes.[98]

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation and diagnosis of ARDS are fundamentally related to the syndrome's pathophysiologic changes, regardless of the underlying etiology. A brief description of the pathology and pathophysiology is provided before a detailed discussion of clinical aspects of the disorder. The reader is also referred to Chapter 140 for additional details on disease mechanisms.

Pathology and Pathophysiology

A number of interrelated mechanisms contribute to the development and clinical course of ARDS. Inflammatory cytokines, oxygen radicals, activation of coagulation and complement, platelet and immune cell activation, generation of proteases, and abnormal fluid fluxes resulting in edema fluid generation and defective epithelial alveolar fluid clearance have all been hypothesized to play a role in the early stages.[99,100] In addition, factors specific to apoptosis, edema fluid resolution, and fibrosis and repair, as well as the response to mechanical ventilation are likely to play a role in the pathophysiology of the later phases of ARDS.

Pathologically and clinically, ARDS can be divided into *early* and *late phases* of lung injury (Fig. 141-1).[101–104] In the early phase (first few hours or days), light microscopy shows interstitial and alveolar edema, capillary congestion, and intra-alveolar hemorrhage with minimal evidence of cellular injury. Electron microscopy reveals changes of endothelial cell swelling, widening of intercellular junctions, increased numbers of pinocytotic vesicles, and disruption and denudation of the basement membrane. Inflammatory cell infiltration of the lung interstitium may also be seen. Protein-rich pulmonary edema and its clinical effects are most pronounced in the early exudative phase. Hyaline membranes containing condensed fibrin and plasma proteins form over the next several days. Later, in the exudative phase, inflammatory cells become more numerous within the lung interstitium, and extensive necrosis of type I alveolar epithelial cells is present. Pathologists refer to this constellation of findings as *diffuse alveolar damage* (DAD). While DAD is considered the pathologic correlate of the clinical syndrome ARDS, not all patients meeting the clinical criteria for ARDS have DAD on pathology.[105] In an autopsy study of 356 patients with ARDS, DAD was found in 45%, and was more common in patients with severe ARDS and patients who met clinical criteria for more than 72 h, demonstrating the pathologic heterogeneity of the clinical syndrome.

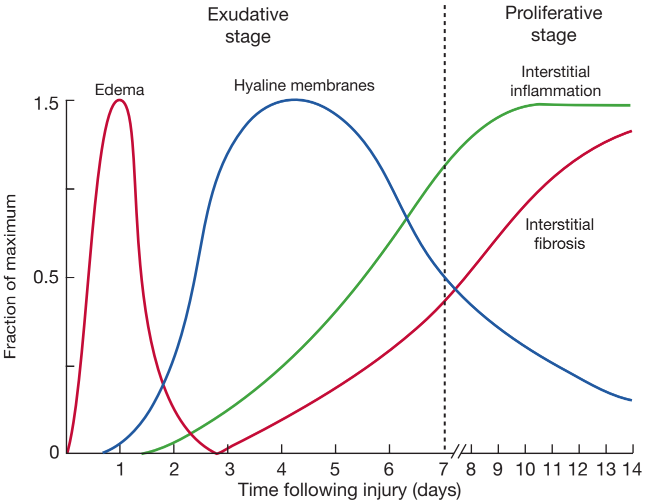

Figure 141-1 Schematic representation showing time course of evolution of the acute respiratory distress syndrome (ARDS). The early or exudative phase is characterized by a pulmonary capillary leak with interstitial and alveolar edema and hemorrhage followed by hyaline membrane formation. Within as short a period of time as 7 to 10 days, a proliferative phase may appear with marked interstitial and alveolar inflammation and cellular proliferation, followed by fibrosis and disordered healing (see text for discussion). *(Reproduced with permission from Katzenstein AA, Askin FB. Surgical Pathology of Non-Neoplastic Lung Diseases. 2nd ed. Philadelphia, PA: Saunders; 1990.)*

Pathophysiologically, in the exudative phase, alveolar edema and alveolar collapse, that is, atelectasis due to loss of normal surfactant-related stabilization of alveoli, interfere with oxygenation.[106,107] Surfactant is washed out of alveoli and inactivated by the alveolar edema. The hypoxemia in ARDS is typically resistant to supplemental oxygen, reflecting an increased right-to-left shunt (Fig. 141-2). Continued perfusion of alveoli that lack ventilation because of alveolar edema results in ventilation–perfusion ratios of zero, thereby defining physiologic shunt. Furthermore, the effects of this type of shunt are exacerbated by shunt-like contributions from alveoli with very low ventilation–perfusion ratios.

Disordered healing and proliferation of fibrous tissue dominate the late phase of ARDS or persistent ARDS, that is, the *proliferative or fibroproliferative* phase. Type II alveolar cells, fibroblasts, and myofibroblasts proliferate in this phase, which can occur as early as 7 to 10 days after initial injury. The late phase of ARDS is characterized by an increased dead-space fraction, high minute ventilation requirement, pulmonary hypertension, and further reduction in lung compliance.[108,109]

Clinical Presentation

The development of ARDS usually follows a rapid course, occurring most often within 12 to 72 h of the predisposing event.[45] At its onset, patients with ARDS often become anxious, agitated, and dyspneic. Inflammatory changes in the lung decrease lung compliance, which, in turn, leads to an increased work of breathing, small tidal volumes, and tachypnea. If breathing ambient air or low-flow supplementary oxygen, patients with ARDS typically have initial arterial blood gas results showing a Pa_{O_2} less than 50 to 55 mm Hg and pulse oximetry recordings of less than 85% arterial O_2 saturation. The hallmark of ARDS is hypoxemia that is resistant to oxygen therapy because

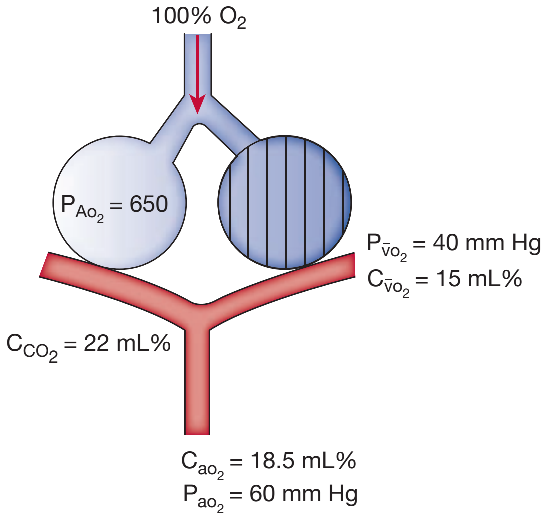

Figure 141-2 Diagram of a two-compartment model of lung perfusion and ventilation demonstrating basis for failure of oxygenation in ARDS. When large portions of the lung are nonventilated due to alveolar collapse or flooding (hatched area), blood flow to these units with mixed venous P_{O_2} ($P\bar{v}_{O_2}$) of 40 mm Hg and content of 15 vol. percent is effectively "shunted" through the lungs without being resaturated. Thus, despite a high concentration of supplemental oxygen (100% in this example) and high alveolar P_{O_2} in ventilated unit, these blood flows mix in accord with their oxygen contents, that is, the resulting left atrial blood has an oxygen content that is the weighted mean of the oxygen content of the shunted and nonshunted blood. In this example of a 50% shunt, the left atrial and systemic arteries have an arterial P_{O_2} of 60 mm Hg. Ca_{O_2}, arterial oxygen content; C_{CO_2}, capillary oxygen content; $C\bar{v}_{O_2}$, mixed venous oxygen content; PA, alveolar pressure; Pa_{O_2}, arterial P_{O_2}; $P\bar{v}_{O_2}$, partial pressure of oxygen in the mixed venous blood. *(Reproduced with permission from Hall JB, Schmidt GA, Wood LDH: Principles of Critical Care, 3rd ed. New York, NY: McGraw Hill; 2005.)*

of the large right-to-left shunt (Fig. 141-2). Initially, patients may be able to compensate by hyperventilating, thereby maintaining an acceptable Pa_{O_2} with an acute respiratory alkalosis. Typically, patients deteriorate over several hours, requiring endotracheal intubation and mechanical ventilation.

Differential Diagnosis

The differential diagnoses for acute hypoxemic respiratory failure, in general (Table 141-5), and for ARDS, in particular (Table 141-6), are extensive.[110,111] Identifying the specific etiology of the diffuse infiltrates in ARDS is important because several causes, for example, acute eosinophilic pneumonia or diffuse alveolar hemorrhage, have specific therapies. Table 141-6 lists the major clinical and diagnostic characteristics of these disorders.

The setting in which respiratory failure occurs usually provides important diagnostic information. ARDS commonly arise following development of a typical predisposing factor (Table 141-4). Sepsis, pneumonia, trauma, transfusion of blood products, and gastric aspiration account for the majority of cases.[44] When an inciting event is obvious and diagnostic criteria (Tables 141-1A and 141-1B) are met, establishment of a clinical diagnosis of ARDS is not difficult. Under such circumstances, management can be instituted immediately. However, in the absence of a clear predisposing event, or when conflicting or ambiguous information exists, the other causes listed in Table 141-6 should be considered, and relevant clues from the history and physical examination sought. For example, cardiogenic edema is most often accompanied by systolic left ventricular or valvular dysfunction, and the appropriate history and physical findings (e.g., a heart murmur or ventricular gallop) are often present. Electrocardiographic and laboratory-based evidence (e.g., serum troponin I levels) of cardiac ischemia suggest cardiogenic edema as a likely cause. Additional important tests that help to differentiate ARDS from other causes of acute hypoxemic respiratory failure are discussed subsequently.

TABLE 141-5 Differential Diagnosis of Acute Hypoxemic Respiratory Failure (AHRF)

1. ARDS
2. Acute cardiogenic pulmonary edema
3. Bilateral aspiration pneumonia
4. Lobar atelectasis
5. Acute loss of ventilation to one lung due to complete or near-complete obstruction of its mainstem bronchus, e.g., due to a mucus plug or blood clot
6. Loss of ventilation to one or both lungs due to large pneumothorax/pneumothoraces
7. Loss of ventilation to one or both lungs due to large pleural effusion(s)
8. Diffuse alveolar hemorrhage
9. Massive pulmonary embolus
10. Acute opening of a right to left intracardiac shunt resulting in shunting of venous blood to the arterial system without being oxygenated in the lung

ARDS, acute respiratory distress syndrome.

Approach to Clinical Diagnosis

A number of diagnostic methods are extremely valuable in evaluating suspected ARDS. Each is briefly described.

Chest Imaging

The chest radiograph is a simple and widely available test used to assess patients with acute hypoxic respiratory failure. In cases of *established* ARDS, the chest radiograph typically demonstrates findings of diffuse, bilateral alveolar infiltrates consistent with pulmonary edema (Fig. 141-3). However, especially early in the course of the disorder, the infiltrates associated with ARDS may be variable: mild or dense, interstitial or alveolar, patchy or confluent.[7] In addition, the radiographic infiltrates may not correlate well with the degree of hypoxemia. For example, a patient with early ARDS may have profound hypoxemia in the setting of patchy asymmetrical infiltrates that may be interpreted as pneumonia or segmental atelectasis.

Routine chest radiographs cannot reliably distinguish hydrostatic edema, that is, cardiogenic edema, from ARDS. Nonetheless, several criteria suggest *cardiogenic* edema: increased heart size, increased width of the vascular pedicle, vascular redistribution toward upper lobes, the presence of septal lines, or a perihilar (bat's wing) distribution of the edema.[112] Lack of these findings, in conjunction with patchy peripheral infiltrates that extend to the lateral lung margins, suggests ARDS. In the proper clinical setting, despite a variable radiographic appearance, the presence of bilateral infiltrates and moderate or severe hypoxemia ($Pa_{O_2}/FI_{O_2} \leq 300$ mm Hg) should raise the possibility of ARDS. Additionally, computed tomography (CT) scans of the chest tend to demonstrate widespread patchy or coalescent airspace opacities often more apparent in the dependent lung zones.[113] CT scans can augment chest radiograph to further diagnosis of underlying syndromes resulting in ARDS but are often

TABLE 141-6 Differential Diagnosis of ARDS

Disorder	Characteristics	Comments
Pulmonary edema due to left heart failure	History of cardiac disease, enlarged heart on chest radiograph, third heart sound.	Rapid improvement with diuresis and/or afterload reduction.
Noncardiogenic pulmonary edema	History of one or more precipitating causes (Table 141-4), crackles absent or not prominent, normal cardiac size on chest radiograph.	Usual etiology for ARDS. Rarely some patients with ARDS have no obvious precipitating cause.
DAH	Often associated with autoimmune diseases (e.g., vasculitis) or following bone marrow transplantation. Often patients do not have bloody sputum. Renal disease or other evidence of systemic vasculitis may be present. Hemosiderin-laden macrophages in bronchoalveolar lavage fluid can confirm diagnosis of DAH. May respond to apheresis, corticosteroids, or cyclophosphamide, depending on etiology.	May meet diagnostic criteria for ARDS (Tables 141-1A and 141-1B), but has different pathophysiology and management.
Acute eosinophilic pneumonia	Cough, fever, pleuritic chest pain, and myalgia are often present. Patients often do not have peripheral blood eosinophilia, but generally have >15% eosinophils in bronchoalveolar lavage fluid. Usually responds rapidly to high-dose corticosteroid therapy.	May meet diagnostic criteria for ARDS (Tables 141-1A and 141-1B), but has different pathophysiology and management.
Lupus pneumonitis	Usually associated with active lupus. May respond to high-dose corticosteroid therapy or cyclophosphamide.	May meet diagnostic criteria for ARDS, but has different pathophysiology and management.
AIP	Slower onset than ARDS (over 4–6 weeks) with progressive course. However it may present in advanced state, mimicking ARDS.	Associated with >90% mortality. AIP includes Hamman–Rich syndrome.
Pulmonary alveolar proteinosis (PAP)	Slower onset than ARDS (over 2–12 months) with progressive course. Can be treated with whole lung lavage.	Characteristic "crazy paving" pattern on high-resolution CT scan of chest.
Bronchiolitis obliterans with organizing pneumonia (BOOP) or cryptogenic organizing pneumonia	May be precipitated by viral syndrome. Slower onset than ARDS (over >2 weeks) with progressive course. However it may present in advanced state, mimicking ARDS. May respond to high-dose corticosteroid therapy.	
Hypersensitivity pneumonitis	Typically slower onset than ARDS (over weeks) with progressive course. However, it may present in advanced state, mimicking ARDS. May respond to high-dose corticosteroid therapy and removal from offending agent.	
Leukemic infiltration	May be rapid in onset during active disease states. Usually leukemia is clinically apparent.	
Drug-induced pulmonary edema and pneumonitis	May follow use of heroin, other opioids, overdose of aspirin, tricyclic antidepressants, or exposure to paraquat.	May progress to overt ARDS.
Acute major pulmonary embolus (PE)	Occurs acutely, occasionally accompanied by severe hypoxemia that may be resistant to O_2 therapy like ARDS, and by hypotension, requiring pressors, mimicking ARDS with sepsis. Patients typically have risk factors for acute PE and may not have common precipitating causes of ARDS.	Chest radiograph in ARDS should have bilateral infiltrates consistent with pulmonary edema. Chest radiograph in acute major PE may have unilateral or no infiltrates. Acute major PE needs a confirmatory study, e.g., CT scan with pulmonary embolism protocol.
Sarcoidosis	The onset is not acute, but its clinical recognition may be. Oxygenation is often impaired and the chest radiograph can be diffusely abnormal.	Historical features and the frequent presence of hilar adenopathy in sarcoidosis usually eliminate confusion with ARDS.
Interstitial pulmonary fibrosis	The onset is not acute, but its clinical recognition may be. Oxygenation is often impaired and the chest radiograph can be diffusely abnormal.	Prior chest radiographs and a history of chronic and progressive dyspnea characterize the collection of diseases causing interstitial pulmonary fibrosis.

AIP, acute interstitial pneumonia; ARDS, acute respiratory distress syndrome; CT, computed tomography; DAH, diffuse alveolar hemorrhage.

unavailable due to a patients instability or are unnecessary. Findings on lung ultrasound may also assist in the diagnosis of ARDS, particularly when chest radiography and CT scans are unavailable.[114] On lung ultrasound, ARDS is described as multiple B lines, typically with a nonhomogeneous distribution, subpleural consolidations, and variable lung sliding.[115,116]

Laboratory Studies

Although no laboratory test is specific for the diagnosis of ARDS, arterial blood gas analysis is important for confirming the diagnosis.[9] Pa_{O_2}/FI_{O_2} is markedly abnormal in patients with ARDS (Tables 141-1A and 141-1B). In addition to the profound oxygen therapy–resistant hypoxemia that is the hallmark of ARDS, acute respiratory

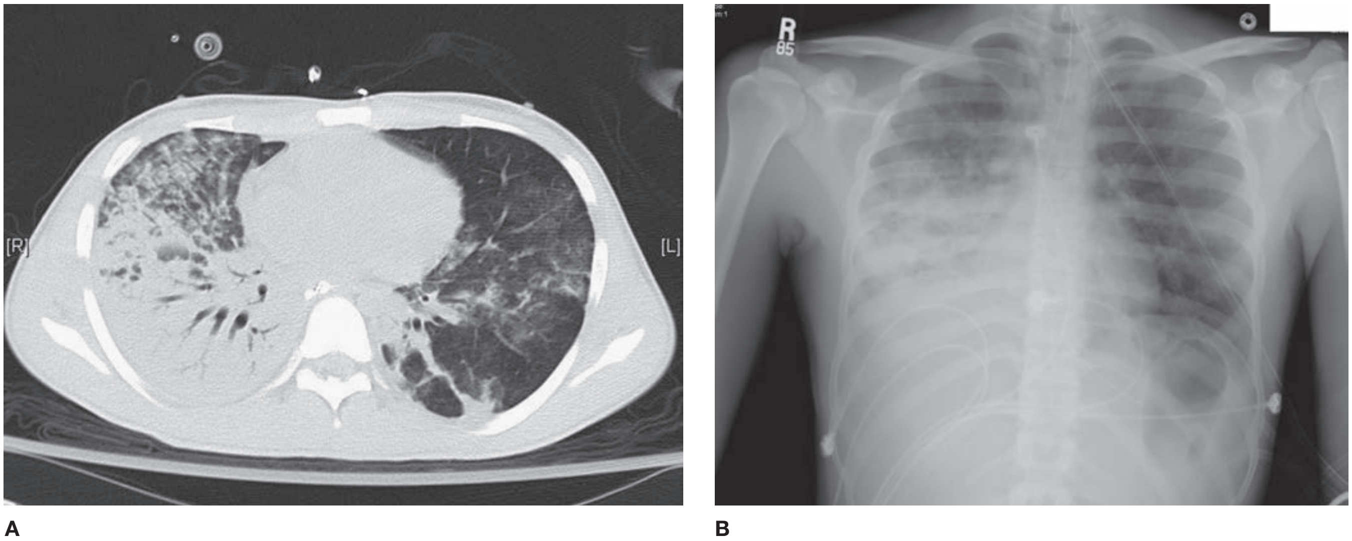

Figure 141-3 Chest CT and plain radiograph in ARDS. **A.** Chest CT scan reveals asymmetric lung injury, with dense consolidation at the right base, patchy alveolar infiltrates in the right anterior lung field, and patchy ground-glass infiltrates throughout the right lung. **B.** Chest radiograph obtained concurrently with chest CT scan shown in panel (**A**). Dense infiltrates at right base, patchy infiltrates in the right upper lung zone, and more subtle infiltrates in the left lung are demonstrated. The panels illustrate the subtle findings of lung injury that are more apparent on the CT scan than on the chest radiograph.

alkalosis may also occur in the early stage. If a patient with ARDS then develops respiratory muscle fatigue, hypercapnia results. In late-stage ARDS, patients typically have increased minute ventilation requirements due to an increasing dead-space fraction, despite possible improvement in oxygen exchange.

In addition to arterial blood gas measurements, several other laboratory studies may be helpful in investigating other causes of respiratory failure and evaluating additional aspects of critical illness associated with ARDS. For example, cardiac enzymes (creatine phosphokinase and troponins) are useful for evaluating the presence of myocardial infarction or cardiac ischemia in patients at risk because of increased age or other factors. The results should be interpreted in conjunction with electrocardiographic findings, since elevations in cardiac enzymes, especially troponins, have been reported in patients with sepsis or septic shock in the absence of coronary artery disease.[117–119]

Another cardiac-related laboratory test that may be useful in this clinical context is plasma brain natriuretic peptide (BNP), which is secreted by the cardiac ventricles, and, to a lesser extent, the atria. BNP measurements are often utilized in the evaluation of acute shortness of breath in patients presenting to an emergency department.[120] In this group, a BNP greater than 500 pg/mL indicates that CHF is likely with a positive predictive value greater than 90%. In the same group, a BNP less than 100 pg/mL suggests that congestive heart is unlikely with a negative predictive value greater than 90%. However, interpretation of an elevated BNP in patients who are critically ill is problematic. Reports indicate that BNP increases with renal failure, and that elevations of BNP greater than 500 pg/mL may occur in patients with sepsis and normal left ventricular function.[121] Nonetheless, one can reasonably exclude a cardiac cause for acute pulmonary edema in patients in the intensive care unit if BNP is less than 100 pg/mL.

Echocardiography

Echocardiography is a useful noninvasive method to evaluate potential cardiac causes of acute hypoxemic respiratory failure.[122] Cardiogenic pulmonary edema is suggested by echocardiographic findings of mitral valve stenosis or regurgitation, left ventricular dilatation and systolic dysfunction, or regional left ventricular wall motion abnormalities. Although these findings do not rule out coexisting lung injury, they are helpful in the initial evaluation and management, even in the presence of ARDS.

Invasive Hemodynamic Monitoring

Although pulmonary artery catheterization was previously performed often in patients with pulmonary edema, the benefits of the procedure are unproven and the risks non-trivial (Chapter 147).[11,123] Several studies have demonstrated that physician interpretation of data obtained from PACs is inconsistent and often erroneous.[124,125] Previous definitions of ARDS have suggested the measurement of PAOP to distinguish ARDS from cardiogenic pulmonary edema;[3] however, the currently accepted Berlin definition of ARDS eliminates such suggestions, recognizing the problems inherent in use of PACs.[9] Studies have demonstrated that many patients who originally met AECC criteria for ARDS (i.e., had a PAOP $\leq$18 mm Hg) often have subsequent measurements with a PAOP $>$18 mm Hg.[12] Furthermore, the Berlin definition recognizes the possibility of concomitant ARDS and cardiogenic edema.

Results of the ARDSNet Fluid and Catheter Treatment Trial (FACCT) support the removal of PAOP criteria from the definition of ARDS, acknowledging that a threshold of 18 mm Hg is arbitrary.[11] FACTT was a large, randomized clinical trial that used a two-by-two factorial design to test a fluid-conservative management strategy against a fluid-liberal management strategy in ARDS. The study also assessed safety and efficacy of a central venous catheter (CVC) or PAC to guide fluid management. In FACTT, 29% of 513 patients enrolled in the PAC arm of the trial were found to have a PAOP greater than 18 mm Hg at the time of initial measurement (following passage of the catheter shortly after enrollment and randomization). Before enrollment, FACTT investigators believed that these patients lacked a primary cardiogenic cause for their pulmonary edema. Approximately one-half of the patients had PAOPs of 19 or 20 mm Hg. Since the vast majority (97%) of this group had a normal cardiac index ($\geq$2.5 L/m^2/min) and a mortality similar to other subjects in FACTT, the elevated PAOP ($>$18 mm Hg) likely reflected intravascular volume loading, rather than cardiogenic pulmonary edema.

Bronchoalveolar Lavage

Bronchoscopy with bronchoalveolar lavage (BAL) is an important tool in the evaluation of patients who have ARDS of unclear origin. In general, BAL can be performed safely in patients with ARDS, except in those with a very low Pa_{O_2} or those requiring high levels of PEEP. The principal reason for performing bronchoscopy in ARDS is to rule in or rule out acute processes that may have specific therapies.

For example, acute eosinophilic pneumonia is a rare disorder characterized by diffuse eosinophilic infiltrates in the lungs (Table 141-6).[126] When the precipitating cause for ARDS is uncertain, performance of BAL and measurement of the percent of eosinophil count in the lavage fluid is helpful in establishing a diagnosis of this corticosteroid-responsive disorder.

Likewise, BAL may be diagnostic for diffuse alveolar hemorrhage (Chapter 68).[127] In this case, the bronchoscopy may or may not reveal fresh blood in the trachea and major bronchi. However, BAL generally demonstrates blood-tinged fluid, which contains red blood cells and hemosiderin-laden macrophages. Diffuse alveolar hemorrhage may occur following bone marrow transplantation or as a result of rheumatologic or other immunologic disorders, including Goodpasture syndrome, granulomatosis with polyangiitis (formerly known as Wegener granulomatosis), systemic lupus erythematosus, or antiphospholipid antibody syndrome.

Lung Biopsy

Routine lung biopsy is not recommended in ARDS; however, lung biopsy should be considered if alternative etiologies of respiratory failure cannot be adequately excluded. While many patients with ARDS are not sufficiently stable to undergo a lung biopsy, the safety of a surgical lung biopsy has been demonstrated in a highly selective group of patients with hypoxic respiratory failure.[128,129] In general, lung biopsy should be reserved for a highly selective group of patients where alternative diagnoses are possible and would significantly change management and prognosis.

APPROACH TO TREATMENT

The general approach to treatment of ARDS includes addressing precipitating causes and other concurrent clinical issues, ensuring adequate oxygenation, careful implementation of a lung-protective ventilator strategy, prudent fluid and hemodynamic management, special patient positioning, and a multitude of other measures, including pharmacologic considerations. Each is discussed subsequently.

■ Goals of Management

Management of patients with ARDS can be complicated and challenging because clinicians are often faced with simultaneous failure of both respiratory and nonrespiratory organ systems (Table 141-7). Unfortunately, only a limited set of controlled clinical trials are available to support an evidence-based approach. For example, even large, multicenter, randomized clinical trials, such as those done by ARDSNet, are limited in the number of variables that can be tested. As a result, patient management rests on a combination of relevant evidence-based medicine, extrapolations from basic and clinical research, and experience-based approaches.

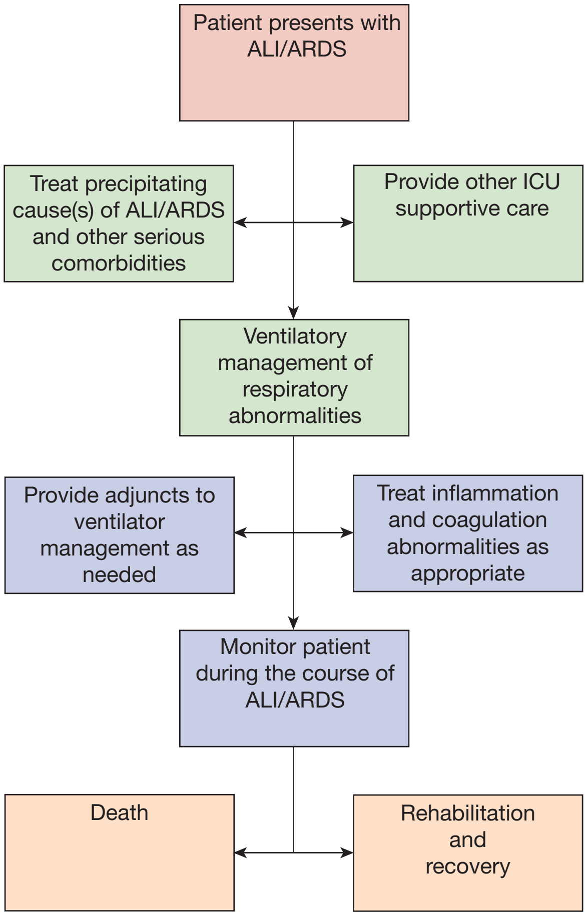
■ Diagnosis and Treatment of Precipitating Causes and Other Comorbidities

The first step in the therapy of ARDS is identification and treatment of the precipitating cause(s) and any other life-threatening medical or surgical issues (Fig. 141-4).

Since ARDS is a *syndrome* based on nonspecific radiographic and physiologic criteria, establishing a diagnosis of ARDS is *not*

TABLE 141-7 Goals of Management of Patients with ARDS

- Treatment of respiratory system abnormalities
  - Diagnose and treat the precipitating cause of ARDS, if possible (Table 141-8)
  - Maintain oxygenation, preferably using nontoxic $F_{I_{O_2}}$ (<0.7), PEEP, or mechanical ventilation
  - Prevent ventilator-induced lung injury (VILI) by using a low tidal volume ventilatory strategy (Table 141-9) with a limit (≤30 cm H_2O) on static end-inspiratory airway pressure (plateau pressure)
  - Keep pH in normal range without compromising goal to prevent VILI (but reverse a life-threatening acidosis, even if it prevents meeting goal to prevent VILI)
  - Enhance patient–ventilator synchrony and patient comfort by use of sedation, amnesia, opioid analgesia, and pharmacologic paralysis, if necessary
  - Liberate or wean from mechanical ventilation when patient can breathe without assisted ventilation
- Treatment of nonrespiratory system abnormalities
  - Support or treat other organ system dysfunction or failure
  - General critical care (preventive and homeostatic measures)
  - Adequate early nutritional support



Patient presents with ALI/ARDS
Treat precipitating cause(s) of ALI/ARDS and other serious comorbidities
Provide other ICU supportive care
Ventilatory management of respiratory abnormalities
Provide adjuncts to ventilator management as needed
Treat inflammation and coagulation abnormalities as appropriate
Monitor patient during the course of ALI/ARDS
Death
Rehabilitation and recovery

Figure 141-4 Summary of treatment approach to ARDS. Note that, "Treat inflammation and coagulation abnormalities as appropriate," is currently limited. *(Reproduced with permission from Hall JB, Schmidt GA, Wood LDH: Principles of Critical Care, 3rd ed. New York, NY: McGraw Hill; 2005.)*

TABLE 141-8 Treatable Inciting Causes of ARDS

- Infectious etiologies
  - Bacterial or other sepsis, e.g., fungemia, responsive to antimicrobial therapy
  - Diffuse bacterial pneumonias, e.g., *Legionella* species
  - Diffuse viral pneumonias, e.g., cytomegalovirus, influenza A
  - Diffuse fungal pneumonias, e.g., *Candida* species, *Cryptococcus*
  - *Pneumocystis jiroveci* pneumonia
- SARS-CoV2 pneumonia
  - Other diffuse lung infections, e.g., military tuberculosis
- Noninfectious etiologies
  - Diffuse alveolar hemorrhage post–bone marrow transplantation
  - Diffuse alveolar hemorrhage due to vasculitis, e.g., Goodpasture syndrome
  - Acute eosinophilic pneumonia
  - Lupus pneumonitis
  - Toxic drug reactions, e.g., aspirin

equivalent to diagnosing the precipitating cause. The fact that early identification and treatment directed at the inciting cause(s) of ARDS are imperative for the resolution of lung injury and respiratory failure cannot be overemphasized. Treatable inciting causes of ARDS include a variety of infectious and noninfectious disorders (Table 141-8).

■ Management of Respiratory Failure

Management of respiratory failure in ARDS rests on assurance of adequate oxygenation and carefully crafted ventilatory strategies, as outlined in the following sections.

Maintaining Adequate Oxygenation

As noted, the pathophysiologic hallmark of ARDS is hypoxemia that is resistant to oxygen therapy. Maintaining adequate arterial oxygenation is the primary goal of both traditional and newer ("lung-protective") approaches to assisted ventilation.

As expected with shunt physiology, administration of supplemental oxygen provided by high-flow oxygenation systems, for example, a nonrebreather facemask or high flow oxygen via nasal cannula, is generally ineffective in reversing the oxygenation deficit. Additionally, concomitant hypercapnic respiratory failure and shock may also lead to the failure of noninvasive oxygenation techniques. Exceptions to this rule are some patients with mild or transient cases of ARDS that are otherwise uncomplicated by other organ system failures. In a randomized controlled trial of 310 nonintubated patients with acute hypoxemic respiratory failure without hypercapnia, altered mental status, or shock, the use of high-flow oxygen through a nasal cannula resulted in a lower hazard ratio for death at 90 days compared with noninvasive ventilation via face mask or standard oxygen therapy.[130] Since many of these hypoxic patients had bilateral infiltrates consistent with ARDS, high-flow oxygen via nasal cannula represents a reasonable first step in this select patient group. This study suggests, however, that the use of noninvasive ventilation via face mask for patients with ARDS should generally be avoided. Another noninvasive alternative to intubation is noninvasive helmet ventilation. While the evidence for helmet ventilation is limited, a small single center randomized controlled trial of 83 nonintubated patients with ARDS demonstrated reduced requirements for invasive ventilation and reduced mortality with noninvasive ventilation via helmet relative to face mask.[131]

Upon intubation, most patients with ARDS require high levels of $\mathrm{FI}_{\mathrm{O}_2}$ to maintain oxygenation; however, high concentrations of oxygen may potentially be toxic. While not studied adequately in patients with ARDS, studies of animals and healthy humans have demonstrated the toxic effects of oxygen therapy within hours of its initiation.[132,133] Given the theoretical concern for oxygen toxicity, PEEP is employed to improve oxygenation by reducing physiologic shunt. When utilized in sufficient amounts, PEEP generally results in some degree of correction of the hypoxemia in patients with ARDS, thereby allowing $\mathrm{FI}_{\mathrm{O}_2}$ to be lowered from high, potentially toxic concentrations. The effect of PEEP-induced improvement in arterial oxygenation is attributed predominantly to recruitment of collapsed alveoli. However, application of PEEP may also mediate a redistribution of alveolar fluid into the interstitium and decrease the absolute magnitude of shunt by reducing cardiac output.

Lung-Protective Mechanical Ventilation

As described in Chapter 140, over the past several decades investigators have convincingly shown that large tidal volumes delivered during mechanical ventilation can injure lungs of normal animals, producing a pathologic pattern resembling ARDS in humans.[134,135]

In animal models of ALI, use of large tidal volume ventilation has been found to augment pre-existing injury. In addition, repetitive opening and closing of alveoli during inspiration and expiration induces ALI in normal animals.[136,137] The injury can be prevented by application of sufficient PEEP. Finally, overexpansion of alveoli in normal lungs of sheep induces multiorgan failure,[138] with studies in other species showing that lung overexpansion results in systemic release of proinflammatory cytokines—providing a likely mechanism for these remote deleterious effects.[139–141] These observations support the concept that the lung is an "engine of inflammation."

Concurrent with the previously described observations, clinical investigators studying patients with ARDS using computed tomography observed that, in contrast to the typical diffuse-appearing pattern noted on plain chest radiographs, the pattern of consolidation, atelectasis, and normal alveoli is actually heterogeneous (Fig. 141-3).[142] The key physiologic implication of these observations is that a ventilator-delivered tidal volume is preferentially distributed to the open alveoli, which represent only a small fraction of the entire lung.[143] In referring to this lung fraction as "the baby lung," investigators emphasized the potential danger of delivering traditional tidal volumes of 10 to 15 mL/kg actual body weight and the associated risk for alveolar overexpansion and lung injury. Notably, tidal volumes of 10 to 15 mL/kg actual body weight (equivalent to approximately 12 to >15 mL/kg predicted body weight) were used originally in critically ill patients with ARDS as a complementary strategy to PEEP in recruiting atelectatic alveoli.

These productive lines of basic and clinical research strongly support the hypothesis that mechanical ventilation using limited tidal volumes should be less injurious to the lungs of patients with ARDS and should result in better outcomes (i.e., decreased mortality) compared with use of traditional, large tidal volume ventilation. Several randomized controlled trials have been conducted to address the role of low tidal volume ventilation in ARDS, including the landmark ARDSNet trial, ARMA, discussed in detail below.[4,144] Meta-analyses of multiple trials support a low tidal volume ventilation approach to reduce mortality in ARDS.[145,146]

In summary, the goals of lung-protective ventilation are to avoid injury due to overexpansion of alveoli during inspiration ("volutrauma") and injury due to repetitive opening and closing of alveoli during inspiration and expiration ("atelecta-trauma") (Fig. 141-5). The injurious effects of mechanical ventilation on the lung have been referred to as ventilator-induced lung injury or "VILI." The

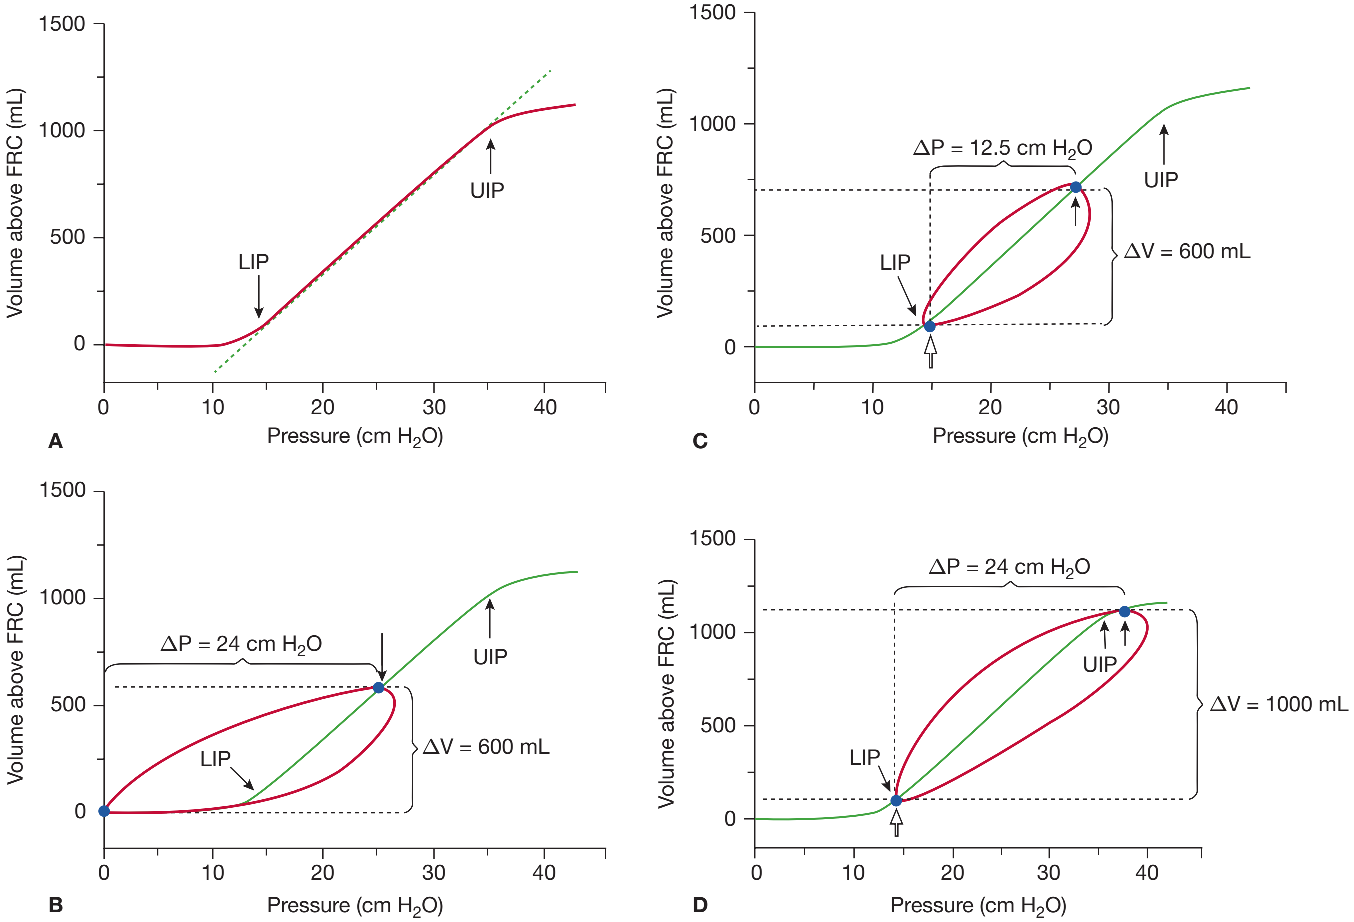

Figure 141-5 **A.** Schematic inspiratory static pressure–volume (P–V) curve of the respiratory system (lung and chest wall combined) in ARDS. Lower inflection point (LIP) is approximately 14 cm H_2O, and upper inflection point (UIP) is approximately 35 cm H_2O. Abscissa is respiratory system recoil pressure; ordinate is lung volume above functional residual capacity (FRC). **B.** Same static P–V curve as (**A**), plus dynamic P–V curve of 600 mL tidal volume starting below the LIP (PEEP = 0). This tidal volume results in a plateau pressure *(closed arrow)* below the UIP (24 cm H_2O). Static compliance (Cstat = ΔV/ΔP = 600 mL/24 cm H_2O) is 25 mL/cm H_2O. **C.** PEEP of 15 cm H_2O has moved the starting point for the 600 mL tidal volume up the static P–V curve to a new FRC *(open arrow)*, which is at the LIP. The tidal volume results in a plateau pressure of 27.5 cm H_2O *(closed arrow)*, which is well below the UIP. Cstat (ΔV/ΔP = 600 mL/12.5 cm H_2O) is increased to 48 mL/cm H_2O. **D.** Dynamic P–V curve of a 1000 mL tidal volume, starting at 14 cm H_2O PEEP, results in a plateau pressure of 37.5 cm H_2O *(closed arrow)*. Despite an increase in Cstat (ΔV/ΔP = 1000 mL/24 cm H_2O = 41.5 mL/cm H_2O), compared with Cstat derived from the 600 mL tidal volume in (**B**), the plateau pressure associated with the 1000 mL tidal volume exceeds the UIP. Delivery of an inflation volume that results in a plateau pressure exceeding the UIP implies alveolar overdistension and is believed to put the lung at risk for ventilator-induced lung injury (see text). *(Reproduced with permission from Lanken PN, Hanson CW III, Manaker S: The Intensive Care Unit Manual. Philadelphia, PA: Saunders; 2001.)*

term “bio-trauma” encompasses the direct lung injury and the concomitant release of inflammatory cytokines that produce remote cell death or organ injury.[147] Clinical strategies underlying contemporary applications of mechanical ventilation in treatment of ARDS are described subsequently.

ARDSNet Ventilator Strategies: Low Versus Traditional Tidal Volumes Based on the aforementioned considerations, the ARDSNet conducted a randomized trial (ARMA) in the mid-to-late 1990s to test the hypothesis that low tidal volume ventilation, combined with limited end-inspiratory (plateau) pressure, would lower mortality and ventilator days among survivors of ARDS compared with use of traditional tidal volumes.[4] The trial included 861 subjects. The low tidal volume arm consisted of a tidal volume of 6 mL/kg predicted body weight, as long as the end-inspiratory pressure (Pplat) was ≤30 cm H_2O; if Pplat exceeded 30 cm H_2O, the tidal volume could be decreased to as low as 4 mL/kg. The traditional tidal volume arm used a tidal volume of 12 mL/kg predicted body weight, as long as the Pplat remained <50 cm H_2O. Both arms included explicit goals and protocols as the bases for ventilator adjustments and determination of the time and means of weaning (Table 141-9).

Important results of the ARMA trial are summarized in Table 141-10. The difference in actual tidal volumes resulted from protocol-driven target tidal volumes in each study arm. As expected, the mean plateau pressure for the lower tidal volume group was <30 cm H_2O (25 cm H_2O), since the protocol required decreasing the tidal volume from 6 mL/kg predicted body weight to as low as 4 mL/kg if Pplat exceeded 30 cm H_2O. Of note, the traditional tidal volume group had a mean Pplat of 33 cm H_2O on study day 1—a value less than the threshold of 35 cm H_2O that some clinicians had believed represented a safe threshold.

Despite the fact that the ARMA clinical trial used an arbitrary threshold of 30 cm H_2O for Pplat in the lower tidal volume arm, it should not be assumed that any Pplat ≤30 cm H_2O is safe. If a “safe” upper limit of Pplat exists, its value is unknown. Lack of such a safe threshold is supported by the finding of an absence of any significant

TABLE 141-9 NIH NHLBI ARDS Clinical Trials Network Low Tidal Volume Ventilation Strategy

Part I: Ventilator Setup and Adjustment

1. Calculate ideal body weight (IBW)[a] (also known as predicted body weight [PBW])
2. Use Assist/Control mode and set initial TV to 8 mL/kg IBW (if baseline TV >8 mL/kg)
3. Reduce TV by 1 mL/kg at intervals ≤2 h until TV = 6 mL/kg IBW
4. Set initial rate to approximate baseline $\dot{V}_E$ (but not >35 bpm)
5. Adjust TV and RR to achieve pH and plateau pressure (Pplat) goals below.
6. Set inspiratory flow rate above patient demand (usually >80 L/min); adjust flow rate to achieve goal of I:E ratio of 1:1.0–1.3

Part II: Oxygenation Goal: Pa_{O_2} = 55–80 mm Hg or Sp_{O_2} = 88–95%

1. Use these incremental $F_{I_{O_2}}$–PEEP combinations to achieve oxygenation goal:

$F_{I_{O_2}}$	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
$F_{I_{O_2}}$	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
PEEP	14	14	14	16	18	20	22	24

Part III: Plateau Pressure (Pplat) Goal: ≤30 cm H_2O

1. Check Pplat (use 0.5-s inspiratory pause), Sp_{O_2}, total RR, TV, and ABG (if available) at least every 4 h and after each change in PEEP or TV.
2. If Pplat >30 cm H_2O, decrease TV by 1 mL/kg steps (minimum 4 mL/kg IBW)
3. If Pplat <25 cm H_2O and TV <6 mL/kg, increase TV by 1 mL/kg until Pplat >25 cm H_2O or TV = 6 mL/kg.
4. If Pplat <20 cm H_2O and breath stacking occurs, one may increase TV in 1 mL/kg increments (to a maximum of 8 mL/kg)

Part IV: pH Goal: 7.30–7.45

Acidosis management: pH <7.30

1. If pH = 7.15–7.30, increase RR until pH >7.30 or Pa_{O_2} <25 mm Hg (maximum RR = 35); if RR = 35 and Pa_{CO_2} <25 mm Hg, may give NaH_{CO_3}
2. If pH <7.15 and NaH_{CO_3} considered or infused, TV may be increased in 1 mL/kg steps until pH >7.15 (Pplat goal may be exceeded) Alkalosis management: pH >7.45: decrease RR, if possible

ABG, arterial blood gas; RR, respiratory rate on ventilator; Sp_{O_2}, Oxygen saturation by pulse oximetry; TV, tidal volume; $\dot{V}_E$, minute ventilation.

[a] *Male IBW, 50 +2.3 (height [inches] – 60); female IBW, 45.5+2.3 (height [inches] — 60).*

interaction between differences in mortality and quartiles of static respiratory compliance or quartiles of plateau pressures (Fig. 141-6). These results suggest that the lower tidal volume ventilatory strategy tends to be effective across a wide range of baseline static compliances and plateau pressures. Likewise, a statistical model of mortality proportion versus day 1 Pplat which combined data from both arms of this clinical trial suggests that, in general, the lower the Pplat, the lower the associated mortality (Fig. 141-7).[148]

These considerations are important, since some clinicians may believe that they can achieve the improved mortality rate simply by

TABLE 141-10 Results of NIH NHLBI ARDS Clinical Trials Network Low Tidal Volume Versus Traditional Tidal Volume Clinical Trial ("ARMA")

Variable or Outcome	Units	Low Tidal Volume Ventilatory Strategy Mean ± SD	Traditional Tidal Volume Ventilatory Strategy Mean ± SD	*p* Value
Tidal volume on day 1	mL/kg PBW	6.2 ± 0.9	11.8 ± 0.8	<0.05
Plateau pressure on day 1	cm H_2O	25 ± 7	33 ± 9	<0.05
PEEP on day 1	cm H_2O	9.4 ± 3.6	8.6 ± 3.6	<0.05
Pa_{CO_2}: $F_{I_{O_2}}$ on day 1		158 ± 73	176 ± 76	<0.05
Pa_{CO_2} on day 1	mm Hg	40 ± 10	35 ± 8	<0.05
Death before discharge or 180 days	%	31.0	39.8	0.007
Breathing without assistance at day 28	%	65.7	55.0	<0.001
No. of ventilator-free days by day 28		12 ± 11	10 ± 11	0.007
No. of days without failure of nonpulmonary systems by day 28		15 ± 11	12 ± 11	0.006

PBW, predicted body weight (see footnote of Table 141-9 for details); PEEP, positive end expiratory pressure; SD, standard deviation; ventilator-free days by day 28, number of days alive and not receiving assisted ventilation between days 1 and 28.

Data from Acute Respiratory Distress Syndrome Network, Brower RG, Matthay MA,et al. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. N Engl J Med. 2000;342(18):1301–1308.

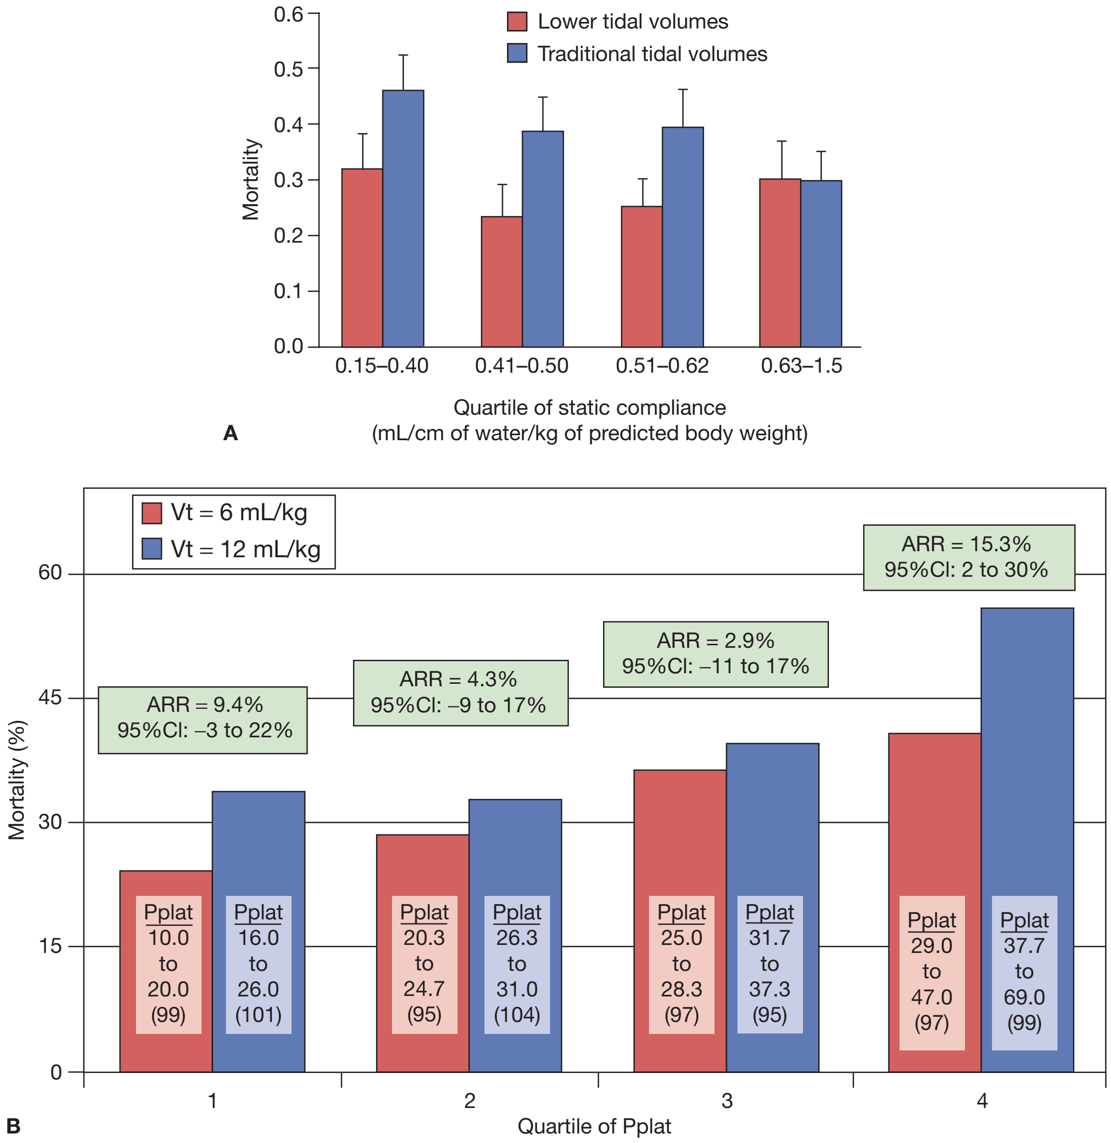

Figure 141-6 ARDSNet ARMA study. Mortality according to quartiles of treatment group (**A**) and end-inspiratory pressure (plateau pressure, Pplat) (**B**) on day 1 in 787 subjects for whom Pplat data are available. Pplat was measured using protocol-dictated tidal volumes. Subjects with the stiffest lungs are likely to have Pplat in the fourth quartile (far right). Range of Pplat (cm H_2O) and number of subjects (parentheses) are shown in each bar of the graph (ARR, absolute risk reduction; CI, confidence interval). Lower tidal volume ventilation appears to benefit patients with ARDS across a range of Pplat. The hypothesis that a "safe" upper limit exists for Pplat, below which ventilator-induced lung injury does not occur, is *not* supported by the data. *(Reproduced with permission from Hager DN, Krishnan JA, Hayden DL, et al. Tidal volume reduction in patients with acute lung injury when plateau pressures are not high. Am J Respir Crit Care Med. 2005;172(10):1241–1245.)*

lowering tidal volumes to the point where Pplat is at or slightly less than 30 cm H_2O, instead of following the ARDSNet low tidal volume strategy of using a tidal volume of 6 mL/kg predicted body weight. In addition, recognition of the need to use predicted, rather than actual, body weight is important, since the latter has been estimated to be about 20% greater than the former (due to fat and extravascular fluid). In summary, clinicians should employ the *entire* ARDSNet protocol (Table 141-9), rather than selected parts in attempting to achieve comparably favorable mortality results.

Lung Protection Due to Higher PEEP The initial ARDSNet trial (ARMA) described earlier did not address the question of whether application of higher levels of PEEP than used traditionally is beneficial.[4] The possibility of improved outcomes using higher levels of PEEP was suggested by both basic and clinical studies conducted in the early 1990s.[5] To address whether higher levels of PEEP combined with low tidal volumes decrease mortality, the ARDSNet conducted a second ventilator clinical trial (ALVEOLI) in which each of two groups received the same low tidal volume ventilatory strategy, but one group was treated using an additional 4 to 5 cm H_2O of PEEP.[37] Mortality rates at day 60 were below 30% for both groups and were not significantly different, even after adjustment for imbalances in baseline variables. Similarly, ventilator-free days were not significantly different.

Subsequently, two further trials were conducted to address the role of a high PEEP strategy, the Lung Open Ventilation to Decrease Mortality in ARDS (LOVS) trial and the Expiratory Pressure Study (EXPRESS).[149,150] Neither study demonstrated a difference in the primary mortality outcomes between the control and intervention groups. However, the high PEEP strategy improved secondary endpoints, including use of rescue therapies in LOVS and duration of mechanical ventilation and organ failure in EXPRESS. More recently, a meta-analysis combined the data from AVEOLI, LOVS, and EXPRESS.[151] Treatment with higher levels of PEEP was not

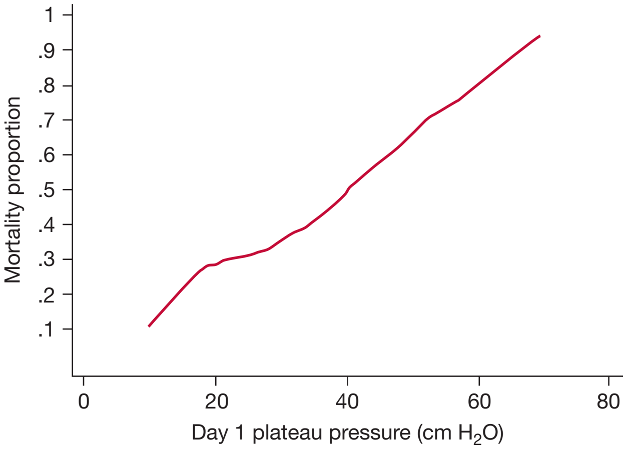

Figure 141-7 Lowess (locally weighted regression and smoothing) plot (bandwidth, 0.4) of mortality proportion and day 1 plateau pressure (Pplat, cm H_2O) for 787 patients enrolled in the ARDSNet ARMA study. Plot includes same subjects and Pplat shown in Figure 141-6. When expressed using this estimating method, the data do not support a safe upper limit for Pplat, the presence of which would be suggested by a leveling in mortality proportion, rather than a further decrease, as the plot demonstrates. The Lowess method is a nonparametric smoother that uses overlapping neighborhoods of data to estimate a local effect. A bandwidth of 0.4 means that 20% of the data on either side of a given Pplat contribute to a local estimate of mortality at that Pplat; data at the high and low ends of the curve represent fewer observations. As data are smoothed using a tricubic weight function, points furthest from the Pplat of interest are assigned the least weight and approach zero. *(Reproduced with permission from Hager DN, Krishnan JA, Hayden DL, et al. Tidal volume reduction in patients with acute lung injury when plateau pressures are not high. Am J Respir Crit Care Med. 2005;172(10):1241–1245.)*

associated with an in-hospital mortality benefit, but among patients with a Pa_{O_2}/FI_{O_2} <200 there appeared to be a reduction in mortality. In addition, other studies have demonstrated that while some patients with ARDS have little or no alveolar recruitment (i.e., opening previously collapsed or fluid filled airspaces) with increased levels of PEEP, others PEEP show marked recruitment.[113] This suggests that future clinical trials using higher PEEP be restricted to subjects with ARDS in whom PEEP increments can reliably result in recruitment.

Amato et al. conducted a retrospective post-hoc analysis of nine previously reported randomized trials evaluating lung protective mechanical ventilation to determine the components of lung protection, such as lower tidal volume, lower plateau pressure, and higher PEEP, that most strongly mediate the reduced mortality.[152] The authors hypothesized that normalizing the tidal volume to the respiratory-system compliance using the driving pressure would better reflect the "functional" size of the lung and therefore be associated with outcomes. The driving pressure represents the tidal volume divided by the respiratory-system static compliance and can easily be calculated on the vent by subtracting plateau pressure minus PEEP. The authors found that of the ventilator variables collected, the driving pressure most strongly associated with survival. Given these data, some have suggested PEEP and tidal volume titration strategies should be aimed at reducing driving pressure. These approaches are currently being evaluated in prospective randomized control trials.[153]

Recommended Core Ventilator Management We recommend that as the core ventilator management in ARDS, clinicians follow the ARDSNet low tidal volume ventilatory strategy (Table 141-9).[4] This strategy includes permissive hypercapnia defined as clinician-allowed hypercapnia during assisted ventilation, despite an ability to achieve a level of minute ventilation sufficient to maintain a normal Pa_{CO_2} with higher tidal volumes. Because higher levels of PEEP have not yet been found to improve outcomes, unless new evidence arises to the contrary, we also recommend that clinicians follow the same combinations of FI_{O_2} and PEEP used in the first ARDSNet trial, ARMA (Table 141-9). Alternatively, clinicians can consider assessing PEEP responsiveness and increasing PEEP in those that demonstrate significant improvements in oxygenation or reductions in driving pressure with the addition of higher levels of PEEP.

Because of constraints of sample size, the ARMA trial tested the low-volume strategy only against use of tidal volumes of 12 mL/kg predicted body weight. Notably, a strategy using 6 mL/kg has not been shown to be superior to a strategy using tidal volumes of 8 to 10 mL/kg. However, based on the previous descriptions of ventilator-induced lung injury (VILI) and biotrauma, we believe it is prudent for clinicians to strictly follow the ARDSNet protocol as their core management strategy in ARDS. Modifications should be considered only in special cases, for example, when contraindications for permissive hypercapnia exist (Table 141-11).

Other Approaches to Ventilator Management

In addition to the low-volume protocol described, several additional approaches may be used in the management of ARDS but lack the level of evidence of the ARDSNet ARMA strategy. These approaches are discussed briefly subsequently.

Pressure Control Mode The ARDSNet low tidal volume strategy used the volume-assist-control mode—a familiar device setting and the only ventilator intervention that has been shown thus far to improve long-term survival in patients with ARDS.[4] However, other modes of ventilation can also provide low tidal volume ventilation, including pressure control ventilation (PCV).

PCV can limit maximal peak airway pressure as well as end-inspiratory pressure (Fig. 141-8A) and, hence, is favored by some clinicians. However, the end-inspiratory pressure in PCV can be underestimated. For example, using PCV with an inspiratory pressure of 30 cm H_2O and a PEEP of 10 cm H_2O, the end-inspiratory pressure is 40 cm H_2O (the sum of the two pressures). Some may misinterpret this combination as equivalent to a Pplat of 30 cm

TABLE 141-11 Contraindications to Permissive Hypercapnia and Acute Respiratory Acidosis

Increased intracranial pressure from any cause (trauma, mass lesion, malignant hypertension)
Acute cerebrovascular disorders, e.g., stroke
Acute or chronic myocardial ischemia
Severe pulmonary hypertension
Right ventricular failure
Uncorrected severe metabolic acidosis
Sickle cell anemia
Tricyclic antidepressant overdose
Patients taking beta-blockers
Pregnancy (due to potential for decreased fetal blood flow from vasodilation-induced steal syndrome; in addition, shift to the right of the O_2 dissociation curve decreases the maternal-fetal gradient for O_2)

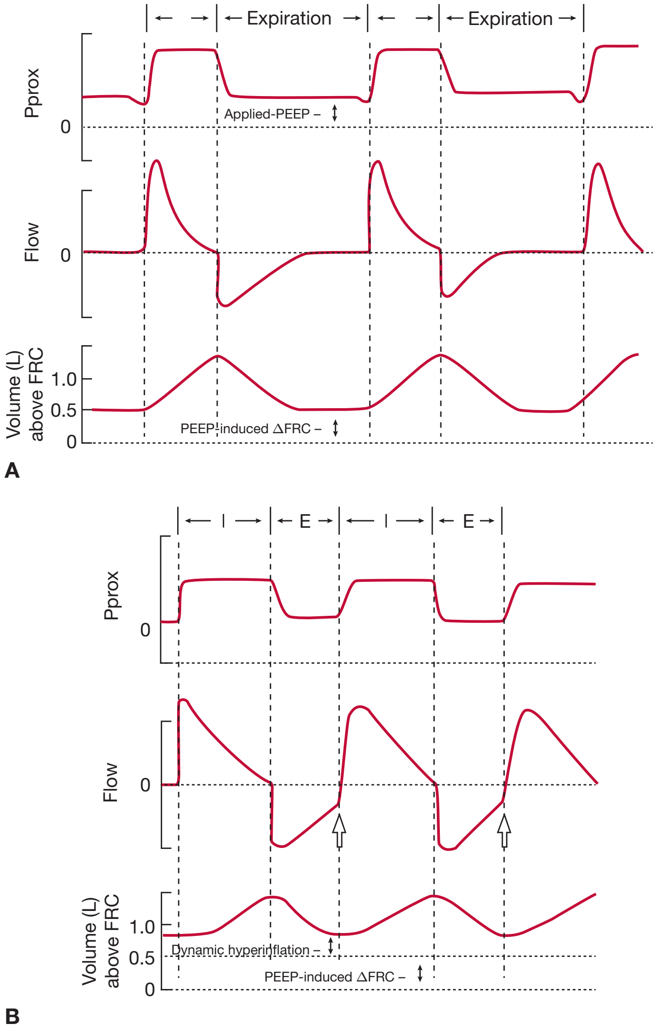

Figure 141-8 Schematic depiction of pressure, flow, and volume waveforms during pressure control ventilation (PCV) with applied PEEP. The x-axis is time and y-axes (from top to bottom) are proximal airway pressure (P_{prose}), inspiratory flow, and volume above functional residual capacity (FRC). Other abbreviations: I, inspiration; ΔFRC, change in FRC. **A.** The inspiratory-to-expiratory (I:E) time is about 1:2. The pressure waveform resembles pressure support ventilation, and the flow pattern is characterized by marked deceleration. Applied PEEP increases FRC (PEEP effect). **B.** I:E time is reversed (I > E), representing pressure-controlled inverse ratio ventilation (PC-IRV). As a result, the next breath starts before expiratory flow has returned to zero *(open arrows)*, resulting in auto-PEEP and dynamic hyperinflation. The latter is superimposed on the increased FRC due to the applied PEEP. *(Reproduced with permission from Lanken PN, Hanson CW III, Manaker S: The Intensive Care Unit Manual. Philadelphia, PA: Saunders; 2001.)*

H_2O and assume that it is a “safe” value according to interpretation of ARDSNet results. As discussed previously, however, no Pplat is known to be safe, even when end-inspiratory pressure is calculated correctly. Furthermore, use of PCV to mimic both tidal volume and Pplat used in the ARDSNet trial remains problematic. The tidal volume delivered at a set pressure in PCV is dependent on the compliance of the respiratory system and is, therefore, variable, particularly in ARDS. The benefit seen from using the ARDSNet strategy may have been due as much to the use of low tidal volume as to lower Pplat. It may be difficult in PCV to ensure tidal volumes are limited, particularly as compliance improves as ARDS improves, which will result in larger tidal volumes at the same set pressure.

TABLE 141-12 “Rescue” or “Salvage” Interventions Used in Patients with ARDS and Severe Hypoxemia Resistant to Conventional Mechanical Ventilation and PEEP

Corticosteroids
Extracorporeal CO_2 removal ($ECCO_2R$)
Extracorporeal membrane oxygenation (ECMO)
High-frequency oscillatory ventilation (HFOV)
Inhaled nitric oxide (NO) or inhaled prostacyclin (epoprostenol/iloprost)
Pressure-controlled inverse ratio ventilation (PC-IRV)
Prone positioning
Recruitment maneuvers

Inverse ratio ventilation (IRV) with PCV is based upon an inspiratory time (I) greater than expiratory time (E), that is, I:E >1 (Fig. 141-8B). Lengthening the inspiratory time increases mean airway pressure because more of the respiratory cycle is spent in inspiration, which may translate into improvements in oxygenation. However, IRV also limits the time for exhalation, potentially resulting in dynamic hyperinflation and auto-PEEP. While increasing auto-PEEP may translate to improved oxygenation, it also results in high pulmonary pressures that may not be lung-protective. IRV with auto-PEEP plus applied PEEP may also compromise cardiac output and increase the risk of nonpulmonary organ dysfunction. Clinicians should consider using PCV–IRV only as a “salvage” mode of ventilation (Table 141-12).

Modes That Allow Spontaneous Breathing During Positive Pressure Ventilation Two ventilatory modes of modern, microprocessor-based devices that permit spontaneous breathing to occur at any phase of the respiratory cycle during assisted ventilation include biphasic airway pressure (BIPAP) and airway pressure release ventilation (APRV). In each, airway pressure cycles between higher and lower levels of PEEP at preset time intervals. APRV represents the extreme of BIPAP whereby patients are given a high level of PEEP to promote alveolar recruitment with a brief release to allow for carbon dioxide removal without allowing alveolar derecruitment. Controlled studies using these ventilator modalities are limited. One report found that the use of APRV in patients with ARDS decreased intrathoracic pressure, improved ventilation–perfusion mismatch and cardiac output, and decreased shunt and dead-space fractions compared with pressure support ventilation (matched for the same airway pressure limits or minute ventilation).[154] However, clinically important outcomes were not compared. Another study performed at a single center in China randomized 138 patients to APRV or lung protective mechanical ventilation.[155] Patients randomized to APRV had more ventilator-free days, a shorter ICU duration, and received less sedation. It is unclear, however, if the study’s findings are generalizable and if they are the result of the application of APRV or an APRV protocol that may have resulted in closer attention being paid to subjects in the intervention arm.

BIPAP and APRV may decrease the use of neuromuscular blocking agents and possibly sedation in patients with ARDS, since both allow spontaneous breathing and potentially less patient-ventilator dyssynchrony. However, whether such modes of ventilation are better than, equal to, or worse than the ARDSNet lower tidal volume ventilatory strategy remains unknown. Until more multicenter clinical evidence supports their superiority or equivalency, their routine use cannot be recommended.

High-Frequency Oscillatory Ventilation High-frequency oscillatory ventilation (HFOV) is a mode of ventilation in which patients are supported with rapid pressure oscillations that generate very small tidal volumes. Theoretically, HFOV may be regarded as the ultimate low-tidal-volume ventilator, with a capacity to ventilate a patient using a very small tidal volume, which lies midway between the upper and lower inflection points of the pressure–volume curve (Fig. 141-5). While commonly used in respiratory distress of the newborn, the use of HFOV in ARDS had previously been limited to centers with necessary ventilatory equipment and technical expertise. Two large, multicenter, randomized controlled trials of moderate to severe ARDS comparing HFOV and traditional care are noteworthy. The trial conducted by the Oscillation in ARDS (OSCAR) study group demonstrated no significant mortality benefit of HFOV compared with usual care, as determined by local practice of participating ICUs.[156] The Oscillation for ARDS Treated Early (OSCILLATE) Trial was stopped early by the Data Safety and Monitoring Committee, as the HFOV group appeared to have a higher in-hospital mortality compared with a low tidal volume, high PEEP control group.[157] While some clinicians previously used high-frequency ventilation as a “salvage” mode (Table 141-12), its use, even in those circumstances, is not supported by controlled clinical trials.

Adjuncts to Lung-Protective Mechanical Ventilation

A number of adjunctive measures to mechanical ventilation have assumed importance in the management of patients with ARDS. In some cases, the physiologic or pharmacologic basis for the measure’s beneficial effect is apparent; in others, the mechanism is unknown.

Overview The use of many adjuncts to lung-protective ventilation is based on extrapolations from animal studies, or from clinical studies using physiologic markers as surrogates for clinically meaningful endpoints, for example, mortality or ICU length of stay or ventilator-free days. However, extrapolation from such studies to clinical practice is problematic. For example, the ARDSNet low tidal volume ventilatory strategy has a demonstrated mortality benefit but also resulted in patients in the low-volume group having significantly lower Pa_{O_2}/FI_{O_2} after enrollment compared with those receiving traditional tidal volume ventilation (Table 141-10).[4] If the trial had used improvement in Pa_{O_2}/FI_{O_2} as a surrogate marker for better survival, the results would have been interpreted as showing that low tidal volume ventilation results in *higher*, rather than *lower*, mortality.

While several adjunctive therapies are employed in ARDS, the most common therapies applied to select patients are prone positioning, neuromuscular blockade, corticosteroids, and conservative fluid management.[38,158–161] The data supporting each of these therapies range from strong to controversial and are discussed further below. Additionally, extracorporeal oxygenation (ECMO) is increasingly being employed at specialized centers for patients with the most severe forms of ARDS.[162,163] Data supporting the use of other adjunctive therapies in ARDS is lacking and thus, these interventions should be used cautiously, if at all.

Prone Positioning It has long been recognized that placing patients in a prone position improves oxygenation in a majority of patients with ARDS.[164] However, managing critically ill patients in the prone position is challenging and requires special attention to prevent pressure necrosis of the nose, face, and ears. Extra care is also needed to ensure security and patency of the endotracheal tube, central lines, and arterial lines. Pressure on the eye may result in retinal ischemia, especially in hypotensive patients. Others may experience cardiac arrhythmias or hemodynamic instability when turned prone mandating close monitoring by experienced clinicians during patient positioning.

In the past, prone positioning was largely reserved for the emergency management of severe hypoxemia, and despite clinical trials that demonstrated improved oxygenation in the prone position, older trials failed to demonstrate a mortality benefit.[165] More recently, a meta-analysis examined the effects of prone positioning on all patients with ARDS and a prespecified subgroup with severe ARDS ($Pa_{O_2}/FI_{O_2} < 100$ mm Hg).[166] Prone positioning failed to demonstrate a mortality benefit among all patients with ARDS, but findings suggested a mortality benefit among those with severe ARDS. In 2013, a prospective, randomized, controlled trial comparing prone positioning for at least 16 hours a day to supine positioning in 466 patients with ARDS and $Pa_{O_2}/FI_{O_2} < 150$ mm Hg was published.[160] All patients were enrolled within 36 h of initiation of mechanical ventilation for ARDS and were managed with a low tidal volume ventilation strategy. The large majority of the patients in the prone and supine arms were also managed with heavy sedation, vasopressors for shock, and neuromuscular blockade. The primary outcome, 28-day mortality, was 16% in the prone group and 32.8% in the control group, a statistically significant reduction in mortality.

The mechanisms by which prone position may confer a survival advantage in ARDS are not definitely known; however, there is significant experimental evidence that placing a patient in the prone position results in improvements in ventilation-perfusion relationships and reduction in ventilator induced lung injury.[167] Computed tomography studies have demonstrated that patients placed in the prone position have lung inflation that is more homogeneous from dorsal to ventral than in the supine position. This homogeneously distributed ventilation distributes stress and strain and reduces both over-distention and atelectasis limiting ventilator induced lung injury. It is hypothesized that this mechanism among others contributes to the benefits of prone positioning in moderate to severe ARDS. In the past several years, the use of prone positioning in moderate to severe ARDS has becoming increasingly routine and should be considered in all ARDS patients with a $Pa_{O_2}/FI_{O_2} < 150$ mm Hg, at centers with the necessary staff and expertise.

Neuromuscular Blocking Agents Significant controversy exists regarding the role of neuromuscular blocking agents in ARDS with the two largest randomized controlled trials producing conflicting results.[158,159] These agents are frequently used to promote ventilator synchrony and improve oxygenation in moderate to severe cases of ARDS; however, they have been associated with prolonged neuromuscular weakness in survivors of ARDS.

In a multicenter study, 340 heavily sedated patients with ARDS and a $Pa_{O_2}/FI_{O_2} < 150$ were randomized to 48 h of cisatracurium or placebo early after ARDS onset.[158] The 90-day mortality rate was 31.6% in the cisatracurium group and 40.7% in the placebo group, a finding that was only statistically significant after adjustment for baseline Pa_{O_2}/FI_{O_2}, baseline plateau pressure, and the Simplified Acute Physiology II score. Although not powered for this outcome, ICU-acquired neuromuscular weakness was not different between the groups. Unlike other paralytics, cisatracurium is largely metabolized by Hofmann elimination and is mostly independent of liver and renal dysfunction, both of which are common in ARDS. One significant limitation to this study was both the intervention and control arms were heavily sedated. The Reevaluation of Systemic Early neuromuscular blockade (ROSE) trial, published in 2019, sought to address this limitation by comparing early neuromuscular blockade with cisatracurium to a usual care strategy that attempted to limit sedation as much as possible.[159] The study included 1006 patients with ARDS and a $Pa_{O_2}/FI_{O_2} < 150$ randomized to heavy sedation and cisatracurium for 48 h versus usual care including limited sedation. The lung protective ventilator strategies were the same in both arms. Mortality at 90 days was nearly identical in the two arms (42.5% in the intervention arm versus 42.8% in the control arm), suggesting neuromuscular blockade does not benefit ARDS patients over usual care and reduced sedation. A significant limitation to the ROSE study was that less than 15% of patients underwent prone positioning despite the evidence for its use.[160] Based on the current available evidence, neuromuscular blockade should not be used routinely in all patients with moderate to severe ARDS. It may, however, be beneficial in select patients, such as those with severe ventilator dyssynchrony, or to facilitate placing and maintaining a patient safely in prone position.

Corticosteroids The use of corticosteroids in ARDS remains controversial despite being the subject of clinical research for over 30 years. The theoretical benefits of corticosteroids include reducing inflammation and fibrosis, key components of both the acute and proliferative phases of ARDS.[168] Despite these theoretical benefits, corticosteroids also have potential downsides, including increased secondary infections, hyperglycemia, delirium, and long-term neuromuscular weakness. There is increasing evidence, however, for the use of corticosteroids in critically ill populations that overlap with ARDS, including severe community acquired pneumonia and septic shock.[169,170] Therefore, corticosteroids use in ARDS has increased over time with unclear benefit.

Initial studies of high dose methylprednisolone failed to demonstrate a consistent benefit early in ARDS, leading researchers to hypothesize that moderate dose methylprednisolone may benefit patients with persistent ARDS.[171] In 2006, the ARDSNet investigators published results of a double blind, randomized, controlled clinical trial (Late Steroid Rescue Study or LaSRS) designed to evaluate benefits and risks of moderate doses of methylprednisolone in 180 patients with persistent ARDS (ARDS lasting 7–21 days).[172] The study revealed no differences in 60- or 180-day mortality rates. Although parameters of respiratory function and time to liberation from mechanical ventilation improved after corticosteroid administration, the corticosteroid treated group included more patients who required re-intubation. Furthermore, no statistically significant differences between treated and untreated groups in ICU or hospital days by 180 days were observed. In addition, more adverse events related to weakness occurred in the treated group than in those receiving placebo. Finally, patients treated with corticosteroids after 14 days of persistent ARDS had a significantly increased mortality. Hence, the results of this study do not support the routine use of steroids for late-phase ARDS in general, and they argue against their use if ARDS has been present for 14 days or longer.

More recently, investigators published the results of a randomized controlled trial of high dose dexamethasone in patients with moderate or severe ARDS ($Pa_{O_2}/FI_{O_2} < 200$).[161] In total, 277 patients enrolled at 17 ICUs in Spain were randomized to dexamethasone 20 mg intravenously daily for 5 days followed by five days of 10 mg daily or usual care. Importantly, the dexamethasone was administered unblinded with no placebo administered in the usual care group. The 60-day mortality was 21% in the interventional group and 36% in the control group ($p = 0.005$), suggesting a mortality benefit to the steroid regimen. It remains unclear, however, if the study results were impacted by the un-blinding of treating clinicians.

Several questions remain regarding the usefulness of corticosteroids in the routine care of ARDS. The benefit of a particular corticosteroid over another or a particular dosing regimen over another remains unknown. Additionally, the long-term impact of corticosteroid use is unclear. Based on the available evidence, it is reasonable to consider corticosteroids in patients with moderate or severe ARDS, early in their course, who have not responded to initial therapies. Corticosteroids should also be administered to patients with non-ARDS indications, such as *Pneumocystis carinii* pneumonia or acute eosinophilic pneumonia. Lastly, corticosteroids should be avoided in patients who have met ARDS criteria for greater than 14 days.

Fluid Management The ARDSNet Fluid and Catheter Treatment Trial (FACTT), noted previously, used a two-by-two factorial design to test the hypothesis that a management strategy of fluid restriction (conservative fluid management) would improve clinically important outcomes in ARDS compared with more generous fluid management strategy (liberal fluid management).[38] Although the strategy of liberal fluid management was based upon a protocol to determine fluid balance, patients' net fluid balance during the first 7 days of the trial resembled that resulting from the non-protocol-directed care in the first two ARDSNet clinical trials (ARMA and ALVEOLI).[4,37]

FACTT investigators developed a detailed fluid management protocol that, except for patients in shock (mean arterial pressure [MAP] <60 mm Hg or on vasopressors for hypotension), used four basic input variables (assessed every 1–4 h) to determine the fluid management instructions: (1) MAP; (2) urine output; (3) effectiveness of circulation; and (4) intravascular pressure (central venous pressure [CVP] or PAOP). In both arms of the study, the protocol goals were MAP greater than 60 mm Hg (or vasopressor independence); urine output greater than 0.5 mL/kg predicted body weight/hour; and evidence for effective circulation, including a cardiac index of at least 2.5 L/min/m^2 in patients with PACs or, in those with CVCs, absence of physical examination findings indicating hypoperfusion of extremities. In the group randomized to conservative fluid strategy, the target intravascular pressure was a CVP less than 4 mm Hg or PAOP less than 8 mm Hg. In contrast, for those randomized to the liberal fluid strategy, targets were a CVP of 4 to 8 mm Hg or PAOP of 8 to 12 mm Hg.

Despite marked differences in cumulative net fluid balance between the conservatively and liberally managed groups, the two showed no statistically significant difference in mortality at 60 days, which was the study's primary outcome (Table 141-13). Nonetheless, compared with the liberal strategy, the conservative strategy resulted in statistically significant improvements in several clinically important outcomes, including decreased duration of assisted ventilation and length of stay in the intensive care unit (Table 141-13). Moreover, the conservative strategy did not worsen the incidence of shock, number of days in shock, frequency or extent of other organ system failures, or rate of use of dialysis. In a long-term follow-up study of some of the survivors of the FACTT trial, randomization to a conservative fluid-management strategy was associated with increased cognitive impairment.[173] While not definitive, these findings highlight the lack of long-term outcomes in the majority of published clinical trials in ARDS. The results of the FACTT trial supports the use of a conservative fluid strategy in managing patients with ARDS who are not in shock; however, the impact on long-term outcomes is unknown.

Hemodynamic Management Using the trial's two-by-two factorial design, the ARDSNet FACTT investigators also compared the safety and efficacy of PACs with CVCs in directing fluid and hemodynamic protocols, as described.[11] Mortality and other important clinical outcomes, such as ventilator-free days, ICU-free days, and organ failure–free days by study day 28 were no different in patients managed with a PAC versus a CVC (Table 141-14). However, use of a PAC was associated with a significantly higher complication rate during catheter insertion—primarily, cardiac arrhythmias. The excess events were attributed principally to the need for passing both a sheath and catheter; none of the adverse events was fatal.

Based on the results, the FACTT investigators recommend using a CVC to guide a hemodynamic and fluid management. The use of

[a] *This was an a priori secondary outcome. Death at 60 d was the primary outcome.*

[b] *Cardiovascular failure, systolic blood pressure <90 mm Hg, or receiving a vasopressor other than dopamine at 5 μg/kg/min or less; CNS failure, Glasgow Coma Scale of 12 or less; renal failure, serum creatinine ≥mg/dL (177 μmol/L); hepatic failure, serum bilirubin ≥2 mg/dL (34 μmol/L); coagulation abnormalities, platelet count of 80,000/μL or less. Number of days without organ failure is determined by subtracting the number of days with organ failure from the lesser of 28 or from number of days until death.*

[c] *This difference was not significant from day 1 to day 28.*

[d] *This difference was still statistically significant from day 1 to day 28.*

Data from National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network, Wiedemann HP, Wheeler AP, et al. Comparison of two fluid-management strategies in acute lung injury. N Engl J Med. 2006;354(24):2564–2575.

the PAC in the United States had been declining, even prior to the publication of the FACTT trial, as evidence had been accumulating against routine use.[10] However, clinicians may elect to use a PAC in selected circumstances, for example, determining the adequacy of cardiac output in mixed shock, measuring the oxygen saturation of mixed venous blood, calculating the degree of intrapulmonary shunt, or searching for equalization of diastolic pressures during suspected cardiac tamponade.

Recruitment Maneuvers Lung recruitment maneuvers are defined as the application of CPAP aimed at "recruiting" or opening totally or partially collapsed alveoli. The alveoli are then kept inflated during expiration using an appropriately high level of PEEP. In one study of a "lung-protective" strategy utilizing low tidal volume ventilation and extra-high PEEP, recruitment maneuvers were performed by maintaining a CPAP level of 35 to 40 cm H_2O for 30 s.[149] Others advocate application of equivalent or higher pressures for longer periods.

No controlled clinical trial supports the efficacy of recruitment maneuvers alone to improve clinically important outcomes, such as mortality or ventilator-free days. Studies of recruitment maneuvers have generally used physiologic end points, for example, improvement in oxygenation.[174,175] In a subset of patients treated with high levels of PEEP in the ARDSNet trial comparing high versus low PEEP in ARDS, no clinically relevant improvements in arterial saturation were noted.[176] However, complications, such as transient hypotension and slight drops in arterial saturation during the maneuver, were reported. On the other hand, other clinical studies have reported that recruitment maneuvers improve oxygenation in patients on relatively low levels of PEEP, receiving large tidal volumes, or maintained on paralytics.

The Alveolar recruitment in ARDS (ART) trial, published in 2017, tested a ventilator management strategy that paired a lung recruitment maneuver with aggressive PEEP titration according to the best respiratory-system compliance against a conventional low-PEEP strategy.[177] The 28-day mortality was statistically higher in the experimental group (55.3%) when compared to the control group (49.3%). Additionally, the experimental lung recruitment strategy increased the risk of barotrauma and the need for vasopressors or hypotension in the first hour, raising significant concerns regarding the safety of such a strategy. Because no controlled clinical trials demonstrate efficacy in clinically relevant end points, and because there are potentially harmful adverse effects, routine use of recruitment maneuvers is not recommended in ARDS. Likewise, in the absence of data showing efficacy, routine use of ventilator "sighs" exceeding peak pressures of 30 cm H_2O (the threshold used in the ARDSNet clinical trial that showed improved survival) is also not recommended. Some clinicians may use recruitment maneuvers with higher pressures as part of salvage therapy for patients with severe refractory hypoxemia (Table 141-12).

Inhaled Nitric Oxide In 1993, Roissant et al. published a study of inhaled nitric oxide (NO) as a novel therapy for ARDS.[178] Given via inhalation, NO selectively vasodilates pulmonary capillaries and arterioles that serve *ventilated* alveoli, diverting blood flow to these alveoli and away from areas of shunt. Lowering of the pulmonary vascular resistance, accompanied by lowering of the pulmonary

TABLE 141-14 Results of ARDSNet FACTT (Fluids and Catheter Treatment Trial): Use of Pulmonary Arterial Catheter (PAC) Versus Use of Central Venous Catheter (CVC) to Direct Fluid and Hemodynamic Management Protocols

Result	Pulmonary Artery Catheter Group ($n = 13$)	Central Venous Catheter Group ($n = 87$)	p Value
Death at 60 d (%)	27.4	26.3	0.69
Ventilator-free days from day 1 to day 28[a]	13.2 ± 0.5	13.5 ± 0.5	0.58
ICU-free days from day 1 to day 28[a]	12.5 ± 0.5	12.0 ± 0.4	0.4
Number of catheters inserted[b]	2.47 ± 0.05	1.64 ± 0.04	<0.001
Number of complications per catheter	0.08 ± 0.01	0.06 ± 0.01	0.35
Total number of catheter-related complications per group[b]	100	41	

Plus–minus values are means ± SE.

[a] *This was an a priori secondary outcome. Death at 60 d was the primary outcome.*

[b] *This includes the sheath for PAC, PAC, and CVC for subjects in the PAC group and sheath (n = 6) and CVC for subjects in the CVC group.*

Data from National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network, Wheeler AP, Bernard GR, et al. Pulmonary-artery versus central venous catheter to guide treatment of acute lung injury. N Engl J Med. 2006;354(21):2213–2224.

artery pressure, appears maximal at very low concentrations (0.1 ppm) in patients with ARDS. Beneficial effects on oxygenation take place at somewhat higher inspired concentrations of NO (1–10 ppm). Rapid inactivation of NO by hemoglobin prevents unwanted systemic hemodynamic side effects, but also requires continuous delivery of gas through the ventilator circuit. Thus, if continuous delivery of NO is interrupted (e.g., during patient transport or due to NO supply exhaustion), precipitous and life-threatening hypoxemia and right-sided heart failure may occur.

Inhaled NO has been studied in several controlled clinical trials in patients with ARDS.[179–181] While demonstrating improvements in oxygenation in some patients, inhaled NO did not improve survival in any of the trials. Based on these trials, the routine use of inhaled NO in ARDS is not recommended. Some clinicians may consider using inhaled NO as a salvage intervention (Table 141-12). However, a much less costly alternative, inhaled prostacyclin (epoprostenol/iloprost), is available. Although less well studied than inhaled NO, inhaled prostacyclin seems to improve oxygenation to the same degree in many patients with ARDS.[182]

Extracorporeal Life Support Extracorporeal Life Support (ECLS) is a therapy that utilizes an external artificial membrane and a mechanical pump to provide gas exchange and systemic perfusion in patients with failure of lung and/or heart function. The use of extracorporeal gas exchange, such as extracorporeal membrane oxygenation (ECMO) or extracorporeal CO$_2$ removal (ECCO$_2$R), is based on the hypothesis that more patients will survive if the lung is allowed to recover from its injury by "resting" using extracorporeal gas exchange temporarily. Although this hypothesis was initially stimulated by the desire to decrease the risk of pulmonary oxygen toxicity, its assessment can now be justified in regard to the techniques' potential roles in reducing VILI.

In the 1970s, a large-scale study on use of ECMO in patients with severe ARDS demonstrated that it offered no survival benefit to patients whose mortality was extremely high (approximately 90%).[183] Similarly, a randomized controlled trial in severely ill patients with ARDS reported in 1994 did not find improved survival using ECCO$_2$R.[184] The therapy received renewed attention during the H1N1 influenza pandemic of 2009.[185] Significant technologic advances, along with a population of previously healthy patients infected with influenza and suffering from severe ARDS, prompted the increased use of ECLS.

More recently, two large contemporary trials examining the utility of ECMO in ARDS have been published.[162,163] The first, the Conventional Ventilatory Support versus Extracorporeal Membrane Oxygenation for Severe Adult Respiratory Failure (CESAR) Trial randomized 180 patients with severe, but potentially reversible, respiratory failure to conventional therapy or referral to a single, specialized ECMO center for consideration for ECMO.[162] Death or severe disability, the study's primary outcome, occurred in 53% of the conventional arm versus 37% of those referred to the ECMO center. Among those referred to the ECMO center, 76% received ECMO. While the study demonstrated a statistically significant finding, the study design makes it impossible to distinguish the effects of the ECMO therapy from those of a specialized referral center. The second trial, the ECMO to Rescue Lung Injury in Severe ARDS (EOLIA) trial randomized 124 ARDS patients receiving mechanical ventilation for less than 7 days and met one of three criteria to receive immediate veno-venous ECMO or continued conventional treatment.[163] The three criteria for enrolment were a $\text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2}$ <50 mm Hg for more than 3 hours, a $\text{Pa}_{\text{O}_2}/\text{FI}_{\text{O}_2}$ <80 mm Hg for more than 6 hours, or an arterial blood pH <7.25 with a Pa_{CO_2} >60 mm Hg for more than 6 hours despite optimal ventilator management. The patients were managed with lung protective ventilation and physicians were strongly encouraged to use neuromuscular blocking agents and prone positioning before randomization. The primary outcome of 60-day mortality occurred in 35% in the ECMO group and 46% in the control group with a relative risk of 0.76, 95% confidence interval 0.55 to 1.04, and $p = 0.09$. Despite an 11% absolute mortality difference, the results did not achieve the pre-specified statistical threshold of 0.05. Crossover to ECMO occurred in 28% of patients in the control group, possibly impacting the results. Given these results, some specialized centers offer ECLS to a highly selective group of adults with severe ARDS and consider the technique as a safe life-saving salvage intervention (Table 141-12).[186]

Other Therapies Several other therapies have been the subject of ongoing research in ARDS, including statins, beta agonists, macrolide antibiotics, mesenchymal stem cells (MSCs), and aspirin.

Given their effects on inflammatory cytokines, statins were investigated as a therapeutic in ARDS, but in several large trials failed to demonstrate a benefit.[187–189]

Beta-agonists stimulate removal of fluid from flooded alveoli by stimulating the epithelial sodium pump and promoting active transport of sodium out of the alveoli (with water following passively according to osmotic gradients) and therefore, were considered as a therapy for ARDS. However, two large, randomized controlled trials failed to demonstrate a mortality benefit from beta agonist.[39,190] One of these trials was actually stopped early for increased mortality among the beta-agonist arm.

Animal studies and an observational cohort study of macrolide antibiotics have suggested they may have a positive effect in

ARDS.[191,192] This evidence requires a prospective clinical trial prior to routine use of macrolides in ARDS.

Preclinical studies have demonstrated promising results with exogenous administration of MSCs resulting in attenuated lung injury and improved tissue repair.[193] Phase 1 and 2 randomized controlled trials have demonstrated safety and feasibility of MSC infusions.[194,195] Several larger trials are planned or ongoing testing the role of MSCs in ARDS.

Both preclinical and observational studies have suggested the antiplatelet and anti-inflammatory drug, aspirin, may prevent the development of ARDS in those at risk.[196,197] However, in the LIPS-A trial, aspirin provided no benefit in preventing ARDS.[81]

CLINICAL COURSE, OUTCOME, AND LONG-TERM SEQUELAE

The clinical course and outcomes of ARDS have been better delineated in recent years. Both pulmonary and nonpulmonary outcomes have been investigated.

Clinical Course and Duration

The course of illness varies considerably in severity and duration among patients. ARDS may last for a few days or even less (e.g., ARDS from opioid exposure, with the patient recovering rapidly after the initial insult). Alternately, ARDS from other causes may last several months and involve a prolonged ICU course. Patients can recover or die at any point in the course of ARDS. Using the new Berlin definition of ARDS, the median duration of mechanical ventilation is approximately 5 days, 7 days, and 9 days for mild, moderate, and severe ARDS, respectively.[9] Up to 25% of patients remain on mechanical ventilation for longer than approximately 2 weeks, many for much longer. Most ARDS-related deaths occur within the first 2 weeks, with one-third occurring by day 7, two-thirds by day 14, and three-fourths to four-fifths by day 28.[33]

The mortality rate of patients on mechanical ventilation after 2 to 4 weeks of persistent ARDS is about 30% over the ensuing 2 to 6 months. These rates are similar to the overall mortality rate (at 180 days) for patients enrolled in ARDSNet clinical trials in which low tidal volume ventilation was used. The findings highlight the importance of continued supportive care in the ICU and vigilance aimed at reducing nosocomial complications.

Causes of Death

Approximately one-third of ARDS-related deaths occur in the first 7 days.[33] Most are related to the underlying disease or injury, that is, to events occurring before the onset of ARDS. The majority of patients who die succumb after 7 days, with these late deaths also commonly due to the underlying injury or illness. Other causes include complications occurring contemporaneously with, or after the onset of, ARDS. The most common cause of death in this group of patients is sepsis, with associated multiple organ system failure. Of note, only a relatively small fraction of patients—10% to 20% of all patients with ARDS—die a respiratory death due to irreversible hypoxemia or refractory respiratory acidosis. Therefore, not surprisingly, clinical trials of interventions aimed selectively at improving gas exchange (e.g., use of inhaled nitric oxide or exogenous surfactant) have not demonstrated improved survival.

Long-Term Sequelae

Recent studies indicate that many survivors of ARDS have medical problems and a compromised quality of life, both of which persist well beyond their initial ICU stay.[198–200] Impaired pulmonary, neurologic, musculoskeletal, cognitive, and psychosocial functions have been documented in survivors of ARDS. Furthermore, survivors have a poorer quality-adjusted survival than do critically ill subjects without ARDS.

Research into these disorders is in the early stages; the etiology and pathophysiology of are incompletely understood. Recognition of the problems affecting survivors of ARDS and referral for appropriate evaluation and therapy constitute important components of overall care. With improved therapy of ARDS resulting in greater survival rates, clinicians should anticipate an increase in the prevalence of long-term sequelae.

Health-Related Quality of Life

Health-related quality of life (HRQL) has become increasingly recognized as important in the evaluation of patient-centered outcomes in recovery from a variety of illnesses. A number of studies have evaluated HRQL in ARDS survivors.[198–205] Tools used to assess HRQL include the Medical Outcomes Study 36-Item Short Form Health Survey (SF-36), St. George's Respiratory Questionnaire, Quality of Well-Being Scale, and Sickness Impact Profile. Each has illustrated impaired quality of life in survivors of ARDS compared with various control populations, including critically ill subjects without ARDS, and patients with chronic diseases (including cystic fibrosis). In general, impairments in HRQL improve over the first 3 months following discharge from the ICU and appear to plateau by 1 year. Studies of interventions to improve HRQL are under way.

Pulmonary Sequelae

Studies of pulmonary function following ARDS are affected by inconsistent disease definitions, methodologic problems due to lack of patient follow-up, and heterogeneity of pre-existing pulmonary diseases. Consequently, a range of lung function impairments has been reported following recovery.[199,200,203,206,207] Although a proportion of survivors of ARDS may have impaired diffusion capacity or restrictive or obstructive abnormalities, restoration of normal lung function occurs in a substantial proportion. In the Toronto ARDS Outcomes study, spirometry and lung volumes improved rapidly among survivors, reaching normal in most subjects by 6 months.[199] Diffusion capacity is mildly impaired in many patients after ARDS, but it may return to normal by 2 to 5 years among survivors.[199,200] Given the severely impaired physical function domains reported in HRQL surveys and the relatively mild pulmonary impairment, investigation has more recently focused on other limitations and causes of symptoms in survivors of ARDS.

Physical and Neuromuscular Sequelae

In the previously noted Toronto ARDS Outcomes study, persistent physical impairment in survivors of ARDS was assessed.[199,200] Despite improvement in pulmonary function at 1 year following their ICU stay, this cohort had low exercise capacity, weakness, and decreased physical quality of life as far as 5 years after their acute illness. Risk factors for these findings included multiorgan dysfunction in the ICU, prolonged duration of ARDS, treatment with corticosteroids during the ICU stay, and increased comorbid disease burden. Although the basis for many of the abnormalities is not clear, a number of patients demonstrated a range of abnormalities, including critical illness polyneuropathy, ICU-acquired myopathy (critical illness myopathy), entrapment neuropathy, and heterotopic ossification.

Cognitive and Psychological Sequelae

Cognitive impairments can cause major limitations in the ability to return to work, affect mood, and lead to increased healthcare expenditures. Study of long-term cognitive function in survivors of ARDS indicates that many have impaired memory, reduced attention, and decreased concentration and processing speed.[173,198–200,208] The abnormalities appear to be associated with the number and severity of hypoxemic episodes in the ICU. Similar to physical abnormalities, cognitive dysfunction appears to be worse in the first 3 months following hospital discharge; it may improve for up to 1 year and then reach a plateau.

Depression and anxiety are frequent following ARDS. Several studies indicate that the prevalence of depression is over 25% following recovery.[209,210] These emotional problems are likely multifactorial, including prior hypoxic brain injury and delirium and subsequent limitation of physical function. In addition, some authors have suggested the presence of a major component of posttraumatic stress disorder (PTSD) in survivors of ARDS.[211] Because these disorders are potentially treatable using pharmacologic, behavioral, and cognitive therapies, clinicians should ask survivors about possible depression and anxiety, which, in turn, may improve HRQL.

Finally, in accord with the concept that the ICU team treats patients, as well as their families, clinicians need to be aware that familial caregivers of patients who are survivors of ARDS experience long-term health effects.[212] In particular, they are at increased risk for emotional distress (associated with various factors, including patient depression) and a lower HRQL over all domains tested on the Medical Outcomes Short Form 36. Clinicians providing long-term follow-up care for patients with ARDS should aim to ensure adequate social and other support for their familial caregivers.

SPECIAL CONSIDERATION: CORONAVIRUS DISEASE 2019 (COVID-19) – RELATED ARDS

In the last months of 2019, a novel coronavirus, designated severe acute respiratory syndrome coronavirus 2 (SARS-CoV2), was identified as the cause of a cluster of severe pneumonia cases in Wuhan, China.[213] Subsequently, SARS-CoV2 spread throughout the world resulting in the ongoing global pandemic that claimed the lives of an estimated 1.8 million persons in 2020, straining health care systems in dozens of countries.[214] The World Health Organization designated the disease resulting from SARS-CoV2 infection Coronavirus Disease 2019 (COVID-19). While the majority of patients who are infected with SARS-CoV2 develop a relatively mild course of disease with mild or no symptoms, many patients develop severe disease, characterized by bilateral infiltrates, profound hypoxia, and acute respiratory failure consistent with ARDS, often followed by septic shock and multisystem organ failure.[213,215–218] The major morbidity and mortality in COVID-19, therefore, is thought to be attributed to acute viral pneumonia that progresses to acute hypoxic respiratory failure and ARDS.

Estimates of the prevalence of severe COVID-19 among SARS-CoV2–infected individuals varies across epidemiologic studies; however, early in the pandemic it was estimated that as many as 20% of patients infected with SARS-CoV2 required hospitalization, and up to 25% of hospitalized patients required intensive care.[213,214,219,220] Among critically ill patients with COVID-19, ARDS is common and the Berlin criteria are met in nearly all patients requiring invasive mechanical ventilation. Observational studies have identified several important risk factors for severe illness driven predominately by advanced age and medical comorbidities.[219–222] While COVID-19–related ARDS have been observed across individuals from all age groups, older age is strongly associated with severity of illness and mortality. Comorbidities associated with worse outcomes include cardiovascular disease, hypertension, chronic lung disease, diabetes mellitus, cancer, chronic kidney disease, and obesity.[213,219–225] Additionally, cigarette smoking and chronic exposure to elevated air pollution are also associated with COVID-19 outcomes similar to non–COVID-19–related ARDS.[53,56,57,226,227] In multiple patient cohorts, male sex has also been associated with severity and mortality of COVID-19.[220,223] In the United States, Black, Hispanic, and Native American individuals have constituted a disproportionally high number of severe cases and deaths attributed to COVID-19 compared to non-Hispanic Whites.[228,229] While the exact reason for this disparity is unknown, it is hypothesized that long-standing racial and ethnic disparities in American society in general and healthcare in particularly account for much of these findings.[230]

The presentation of ARDS in COVID-19 is similar to that of non–COVID-19–related ARDS. It is characterized by the acute onset of bilateral noncardiogenic pulmonary infiltrates and severe hypoxemia. However, early in the pandemic several clinicians reported unique aspects of ARDS in COVID-19. First, investigators described a dissociation between the severity of hypoxemia and relatively well-preserved lung mechanics in some patients with COVID-19–related ARDS.[216,231] This observation led to a debate as to whether COVID-19–related ARDS is "typical" ARDS and if it requires distinct management strategies.[232,233] In a study of 301 patients with COVID-19–related ARDS, median static compliance was 28% higher compared with a historic control population of ARDS unrelated to COVID-19; however, the large majority of static compliances measured in the COVID-19 population were well within the range of those observed in classic ARDS cohorts.[234] Second, while pulmonary microthrombosis is common in ARDS unrelated to COVID-19, coagulation dysfunction has been reported to be particularly common in COVID-19–related ARDS.[234,235] In an autopsy series, lungs from patients who died of COVID-19–related ARDS demonstrate classic diffuse alveolar damage with immune cell infiltration, in addition to widespread endothelial injury and microthrombosis.[236] While endothelial and coagulation dysfunction are common in sepsis-associated ARDS, the microthrombi observed in autopsies of COVID-19 patients were significantly more prevalent when compared with patients who died from influenza-associated respiratory failure. While ongoing research may identify further distinct characteristics of COVID-19–related ARDS, current evidence supports the conclusion that COVID-19–related ARDS largely fits within the heterogenous umbrella of "classic" ARDS.

Given the novelty of the SARS-CoV2 virus, treatment strategies employed for COVID-19–related ARDS are mostly extrapolated from evidence in ARDS prior to the COVID-19 pandemic and include best supportive care measures typical of critical care delivery.[237] Current expert opinion supports the use of a lung-protective mechanical ventilation strategy in all COVID-19–related ARDS patients requiring invasive mechanical ventilation, as well as prone positioning in patients with a $\mathrm{Pa_{O_2}/F{\scriptstyle I}_{O_2}}$ <150 mm Hg at institutions with necessary expertise. In patients with moderate to severe COVID-19–related ARDS, prone positioning has been demonstrated to increases lung recruitment and improve oxygenation, suggesting the findings in the PROSEVA trial can be extrapolated to COVID-19.[160,238] Early in the pandemic, experts disagreed over the role of corticosteroids in COVID-19 leading to multiple, large, well-conducted clinical trials of corticosteroids.[239,240] The largest trial, the Randomized Evaluation of Covid-19 Therapy (RECOVERY trial), randomized 6425 patients hospitalized with COVID-19 to dexamethasone, 6 mg daily for up to 10 days, versus usual care.[239] Overall, dexamethasone reduced 28-day mortality by 2.8% (22.9% in the steroid group vs. 25.7% in the usual care group). Among patients requiring invasive mechanical ventilation at the time of randomization the mortality was even more significantly reduced in the steroid treatment group (29.3% vs. 41.4% for usual care). Subsequently, a meta-analysis of 7 randomized clinical trials, including RECOVERY, evaluating the efficacy of corticosteroids in critically ill patients with COVID-19 also demonstrated a statistically significant reduction in 28-day mortality and did not identify an increase in serious adverse events with corticosteroid treatment.[240] The studies included in the meta-analysis randomized patients to various corticosteroids at various dosages including the higher dose dexamethasone previous used in DEXA-ARDS; however, the optimal corticosteroid, dose, and duration could not be assessed due to the small size of several trials.[161] There was no evidence, however, suggesting that a higher dose of corticosteroids was associated with a greater benefit than a the lower dose employed in the RECOVERY trial. Many other therapeutics aimed at viral replication or the host immune response have been studied in COVID-19, with some demonstrating a potential benefit, including the antiviral remdesivir,[241,242] Janus kinase inhibitor baricitinib,[243] and interleukin 6 inhibitor tocilizumab;[244,245] Other therapies of unknown benefit that are frequently employed in the sickest patients with COVID-19–related ARDS include neuromuscular blockade, inhaled pulmonary vasodilators, and extracorporeal membrane oxygenation.[237,246] With the advent of effective and safe SARS-CoV2 vaccines, the incidence of COVID-19–related ARDS will hopefully continue to drop;[247,248] however, COVID-19 has brought renewed attention to ARDS and a recognition that therapies are sorely needed to prevent and treat critically ill patients impacted by ARDS both during and after the global pandemic.

CHAPTER 142

Chronic Hypercapnic Respiratory Failure: Pathogenesis and Management

Jennifer J. Dorsch
Jorge I. Mora

INTRODUCTION

The respiratory control system is made up of three main components: (1) the central neural respiratory generator, (2) the sensory input system, and (3) the neuromuscular effector system.[1] These three systems work in unison for the purpose of carbon dioxide (CO_2) elimination and oxygen (O_2) uptake. By incorporating sensory and chemosensory input, a ventilatory response to physiologic or neuromuscular stress arises, the goal of which is to produce steady alveolar ventilation, while expending minimal energy to meet a person's metabolic needs.

The alveolar–capillary CO_2 gradient is small. Effective elimination of CO_2 requires an active pump mechanism that preserves this diffusion gradient. This is physiologically achieved by the respiratory system but often requires extrinsic mechanical support in disease states. A large diffusion gradient for O_2 makes O_2 transport simpler and explains why supplemental oxygen administration without pump support is often sufficient.

Disease states that affect neuronal stimulation of the muscles of respiration (e.g., congenital central hypoventilation), muscular function (e.g., neuromuscular disease), respiratory mechanics (e.g., kyphoscoliosis, morbid obesity), or dead space ventilation and respiratory pump efficiency (e.g., chronic obstructive pulmonary disease [COPD]) potentially decrease alveolar ventilation and, correspondingly, impair CO_2 elimination. As a compensatory mechanism in disease states, the body may turn to maladaptive respiratory mechanics or breathing patterns which are inefficient and nonsustainable, ultimately resulting in chronic hypercapnic respiratory failure.

Chronic hypercapnic respiratory failure is defined as a steady state partial arterial CO_2 pressure (Pa_{CO_2}) larger than >45 mm Hg during wakefulness. This value is arbitrary, but it is useful in clinical practice, as it allows for standardization of clinical outcomes. In most patients, rather marked abnormalities in the respiratory control system are required before chronic hypercapnic respiratory failure ensues.

Oftentimes hypercapnia first transiently appears during rapid eye movement (REM) sleep, heralding the forthcoming development of chronic hypercapnic respiratory failure and daytime hypercarbia. Mechanical ventilatory support during sleep, both invasive and noninvasive, may delay and, often, reverse this process by enhancing ventilation, achieving eucapnia, and by unloading respiratory muscles during sleep, leading to increased diurnal ventilatory reserve.

This chapter deals with the pathogenic mechanisms at work in the development of CO_2 retention in diseases characterized by increased pulmonary dead space, neuromuscular derangements, or restrictive processes of the lung and chest wall. The compensatory or adaptive mechanisms that help preserve ventilation (e.g., respiratory chemosensitivity, motor responses to alterations in the mechanics of breathing, intrinsic changes in respiratory muscle strength and endurance) and the decompensating, maladaptive responses that predispose to CO_2 retention (e.g., respiratory muscle wasting and fatigue, a rapid, shallow pattern of breathing) will be discussed, as will the concepts involved and technologies utilized in managing chronic hypercapnia.

PATHOPHYSIOLOGY AND MECHANICS OF VENTILATION

In considering hypercapnic respiratory failure, an understanding of respiratory control mechanisms and mechanics, both normal and abnormal, is paramount.

Neuronal Drive to Breathe

Breathing occurs via both automatic and volitional mechanisms. Breathing pattern, amplitude, and rhythmicity are controlled by the respiratory control center in the ventrolateral medulla, which is composed of the pre-Bötzinger complex (pre-BötC), the Bötzinger complex (BötC), and the rostral ventral respiratory group (rVRG).

While eupneic exhalation in normal states of health is passive, BötC, located in the parafacial respiratory group (pRFG), controls active exhalation during states of increased metabolic demand or blood gas derangements (e.g., exercise, hypercapnia, hypoxia). It does this through the recruitment of expiratory abdominal muscles.[2,3] Nearly spatially indistinct from the pRFG is the retrotrapezoid nucleus (RTN), which receives inputs from carotid chemoreceptors, pulmonary stretch receptors, and the hypothalamus.[4,5] The RTN integrates these stimuli and sends projections to the pre-BötC, thus allowing for alterations in respiratory pattern based on sensory inputs.[6] Interestingly the homeobox transcription factor *PHOX2B*, whose mutations cause congenital central hypoventilation syndrome (see below), which is characterized by the loss of automatic responsiveness to hypercarbia during sleep, is located in the RTN.[7]

The pre-BötC is responsible for automatic inhalation through its intrinsic rhythmogenic properties.[2,6,8] Pre-BötC may be influenced by neuronal inputs from mechanoreceptors and chemoreceptors, thus altering the respiratory pattern; however, this input is not necessary for maintenance of respiration. In addition to sensory inputs, µ-opioid receptors are present on pre-BötC neurons, which are responsible for opiate-induced respiratory depression.[4,9]

The rVRG receives and integrates excitatory impulses from the pre-BötC neuronal network supporting inhalation efforts, inhibitory impulses from the BötC neuronal projections which support exhalation, and inputs from the pontine respiratory group (PRG) which analyze input from the hypothalamus, cortex, and nucleus tractus solitarius[10] prior to emitting an impulse to the spinal phrenic and intercostal inspiratory motoneurons, shaping the inspiratory and expiratory pattern.[6] The neuronal impulse generated in the rVRG travels through cranial and spinal motoneurons to effector muscles. The former tract innervates cranial nerves 3, 4, and 5 which control the diaphragm. Additionally, it contributes to airway dilator functions of the larynx, pharynx and tongue which, when activated, maintain a patent airway and decrease resistance to airflow.[10] The latter tract innervates accessory muscles, including scalene, sternocleidomastoid, pectoralis major, trapezius, and intercostal muscles.[11] Through the PRG's input to the rVRG, respiration is further influenced by cortical control, peripheral sensory information (odor, temperature), and visceral/cardiovascular inputs.[10]

Conditions of Altered Neuronal Functioning

Neuromuscular disease, most commonly amyopathic lateral sclerosis (ALS), causes alterations in the neuronal circuitry affecting respiration. Respiratory failure in ALS is multifactorial. Degeneration of upper and lower motor neurons effectively reduces the transmission of the signal to breathe from the medulla to effector muscles. Additionally, lack of stimulation to the muscles of respiration, particularly the diaphragm, causes muscular weakness and atrophy. Respiratory function remains somewhat intact as the disease progresses due to compensatory mechanisms. A number of hypotheses have been proposed as to how this adaptation occurs, including (1) increased central respiratory output from the medulla, (2) augmentation of intact respiratory motor neurons, (3) increase in size of motor unit through neuromuscular junction plasticity, and (4) greater activation of accessory muscles.[12] However, more research needs to be done to characterize the complex interplay of these mechanisms.

In patients with COPD, regardless of the presence or absence of hypercapnia, neuronal output to the diaphragm and accessory muscles of respiration is increased compared with controls.[13] On average patients with COPD have a respiratory drive that is three times that of healthy subjects, which contributed to the previous proposition that COPD—induced hypercapnia was due to respiratory muscle fatigue.[14] Oxidative stress and sarcomeric injury lead to contractile protein wasting and loss of force generating capacity of diaphragm fibers in patients with COPD, in addition to altered peripheral sensory and chemoreceptor input, resulting in altered neuronal output and further adaptive dysfunction. Hypercapnia is now believed to be ultimately due to the mechanical limitations created by chest wall geometric distortions and respiratory muscle remodeling as muscle fails to compensate for higher end-expiratory volumes. Ultimately, decreased minute ventilation arises.

Respiratory Chemosensitivity

Peripheral chemoreceptors are sensory cells in the arterial circulation that monitor the environment outside of the central nervous system (CNS) for changes in pH, O_2, and CO_2, among other parameters. Two of the best-known chemoreceptors are the carotid bodies, located at the bifurcation of the internal and external carotid arteries, and the aortic bodies, located in the aortic arch. Together, these receptors relay information to the CNS which, in turn, increases inspiratory and expiratory muscle activity in proportion to the severity of blood–gas tension fluctuations. The goal is restoration of blood–gas tensions toward normal by modifying alveolar ventilation.

When adjusted for size, the carotid bodies receive the highest blow flow rate of any organ in the body, which allows for nearly continuous sensing of changes in arterial oxygen (Pa_{O_2}), arterial carbon dioxide (Pa_{CO_2}), pH, and temperature.[5] Carotid bodies are most sensitive to changes in Pa_{O_2}. Aortic bodies, on the other hand, operate under a lower blood flow state and respond mainly to changes in Pa_{CO_2}. Peripheral chemoreceptors register and respond rapidly to changes in arterial pH. For example, up to 50% of the acute hypercapnia-induced increase in respiratory drive is due to peripheral chemoreceptor stimulation; the remaining portion of ventilatory augmentation to hypercapnia is accomplished through direct effects of hypercarbia on central chemoreceptors.[15] Peripheral chemoreceptors transmit this information to the central nervous system where it is integrated and relayed to muscles of respiration, causing an increase tidal volume as well as respiratory rate. Alveolar ventilation is augmented in an effort to return Pa_{CO_2} to steady state levels. Central chemoreceptors located in the RTN monitor extracellular pH and thus, function under steady state conditions, rather than during acute fluctuations, thereby constituting the main central site of CO_2 responsiveness.[4,10]

Alterations in Pa_{CO_2} and Pa_{O_2} both result in increased respiratory drive by affecting timing of respiratory motor activity, as well as respiratory muscle activation. Inspiratory muscles increase the rate of change and peak inspiratory intrathoracic pressure, inspiratory airflow, and tidal volume. Expiratory muscles enhance the rate of expiratory airflow; resistance to inspiratory airflow is reduced in the upper airway muscles.[16–18] Additionally, hypoxia and hypercapnia lead to decreased inspiratory time (T_I) and expiratory time (T_E), thus increasing respiratory rate.[19,20] Reductions in T_E are generally out of proportion to the reduction in T_I, thereby increasing the fraction of the respiratory cycle spent in inspiration.

Hypoxia and hypercapnia differ in their effects on the activity of the inspiratory muscles after cessation of inspiratory airflow—so-called post-inspiratory inspiratory activity (PIIA).[11] Hypoxia increases PIIA in both chest wall inspiratory muscles and muscles that constrict the laryngeal aperture. Accordingly, hypoxia has a braking effect on the rate of expiratory airflow. As T_E decreases with increasing hypoxic drive, end-expiratory lung volume increases. PIIA-induced increases in lung volume increase the caliber of the intrathoracic airways and the O_2 content of the lung. Hypoxia-induced PIIA affects the load on the respiratory muscles in complex fashion; PIIA reduces the inspiratory resistive work of breathing, but increases the inspiratory elastic and expiratory resistive work of breathing. It has been suggested, however, that the net effect of hypoxia-induced PIIA is a reduction in overall energy expenditure during breathing. In contrast, hypercapnia diminishes the PIIA.

Role of Blunted Chemosensitivity in Development of Respiratory Failure

The ventilatory response to chemical stimuli (e.g., changes in arterial pH, CO_2, or O_2) is impaired in patients with COPD due to mechanical limitations: hyperinflation, diaphragmatic flattening, chest wall alterations. Additionally, the physiologic response to derangements in oxygen and carbon dioxide is blunted in these patients. For example, patients with COPD who are chronically hypoxic or hypercapnic were found to have a decreased ventilatory response to either increased hypoxia[21] or hypercapnia.[22]

Blunted chemosensitivity to hypoxia and hypercapnia has been proposed as a premorbid and, perhaps, inherited feature of hypercapnic patients with COPD that contributes to the development of respiratory failure. A study comparing subjects with COPD, with and without hypercapnia, to family members without COPD demonstrated that healthy relatives of hypercapnic patients with COPD have a blunted ventilatory response to hypoxia and hypercapnia as compared to normal relatives of eucapnic patients with COPD.[23] These findings may explain the, at times, perplexing lack of correlation between the extent of lung parenchymal distortion and ventilation (Pa_{CO_2}) (Fig. 142-1).

A long-held belief is that when patients with COPD are exposed to hyperoxia, as with inappropriately high supplemental oxygen administration, their respiratory drive will decrease, resulting in an acute rise in Pa_{CO_2} (hyperoxic hypercapnia). This makes theoretical sense since chronically hypercapnic patients are less responsive to increasing CO_2 levels and, thus, are dependent on relative hypoxia spurring their drive to breath, and in part explains hyperoxic hypercarbia. In addition, and more importantly, hypoxemia causes bronchoconstriction via increases in parasympathetic outflow to airway smooth muscle. Accordingly, relief of hypoxemia causes bronchodilation and increased dead space volume. Increased CO_2 in the setting of hyperoxia is largely due to the loss of this hypoxic vasoconstriction, generating ventilation–perfusion distortion that, in turn, leads to an increase in dead space ventilation at the expense of alveolar ventilation (and unchanged minute ventilation), rather than alterations in ventilatory drive[24] (Fig. 142-2).

Respiratory chemosensitivity to both hypoxemia and hypercapnia declines with age.[25] The decline in chemosensitivity with aging

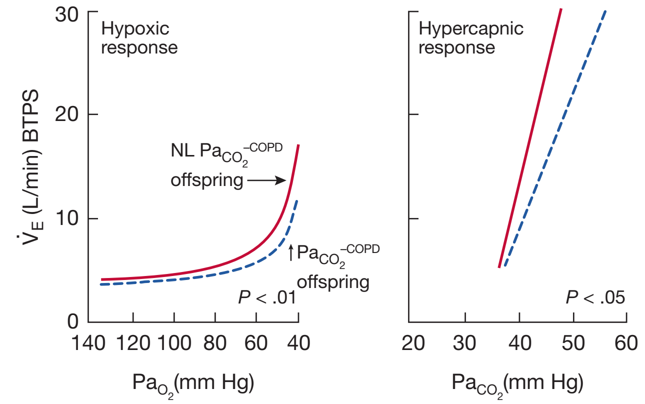

Figure 142-1 Mean isocapnic hypoxia and hyperoxic hypercapnic ventilatory response curves of 12 offspring of hypoventilating patients with COPD *(solid line)* and 10 offspring of eucapnic COPD patients *(dashed line)*. Ventilatory responses to hypoxia and hypercapnia are significantly lower in the offspring of hypercapnic COPD than in the offspring of eucapnic patients with COPD. *(Data from Mountain R, Zwillich C, Weil J. Hypoventilation in obstructive lung disease. The role of familial factors. N Engl J Med. 1978;298(10):521–525.)*

may explain why elderly subjects with lung disease (e.g., COPD) or chest wall disease (e.g., kyphoscoliosis) develop hypercapnic respiratory failure more frequently than young adults. Subjects with the greatest respiratory effort response to changes in Pa_{CO_2} have arterial Pa_{CO_2} values closer to normal than subjects with blunted responses to CO_2, despite the same severity of lung dysfunction. Accordingly, when chemosensitivity is low, subjects with diseases of the ventilatory pump are predisposed to develop hypercapnic respiratory failure. However, since CO_2 retention per se may blunt the response to acute hypercapnia, studies in patients in respiratory failure have not been able to determine whether blunted CO_2 responses are a *cause* or *consequence* of respiratory failure.[26] The important point is that when chemosensitivity is low, subjects are predisposed to develop chronic hypercapnic respiratory failure.[23,27,28]

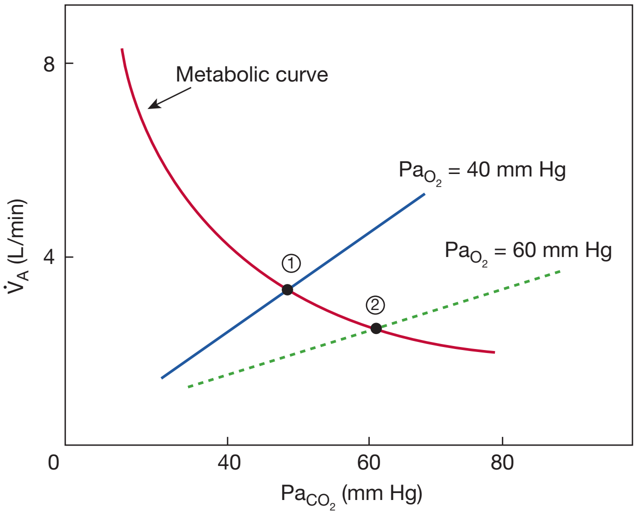

Figure 142-2 Theoretical effects of supplemental O_2 on the ventilatory response to CO_2 and steady-state arterial Pa_{O_2} in subjects with COPD in hypercapnic respiratory failure. Increasing Pa_{O_2} decreases alveolar ventilation and increases Pa_{CO_2} as dictated by effects of O_2 on the CO_2 ventilatory response. The two straight lines represent hypercapnic ventilatory response curves at Pa_{O_2} of 40 and 60 mm Hg. As may be seen, increasing Pa_{O_2} produces a downward, rightward shift of the ventilatory response. In contrast, the hyperbolic line intersecting the ventilatory response lines is the metabolic CO_2–ventilation curve, which represents the effect of increasing alveolar ventilation (independent variable) on Pa_{CO_2} (the dependent variable) when CO_2 production is normal (~200 mL/min). Steady-state alveolar ventilation and Pa_{CO_2} at rest are dictated by intersection of the ventilatory response curves with the metabolic curve (points 1 and 2). Note the increase in Pa_{CO_2} as the ventilatory response with Pa_{O_2} 60 mm Hg intersects at a lower alveolar ventilation and higher Pa_{CO_2} (point 2) compared to the higher ventilatory response when Pa_{O_2} was 40 mm Hg (point 1).

■ Respiratory Muscle Function

The mechanics of breathing require timed, coordinated activation of a number of muscle groups. The primary muscle of respiration is the diaphragm; however, accessory muscles, including the scalenes, intercostals, paraspinals, and sternocleidomastoids, also are recruited under situations of increased respiratory load (e.g., exercise, changes in elastance or compliance of the lung or chest wall, or altered CO_2 or O_2 tension) and contribute to respiratory effort.[29] Contraction of the muscles of the upper airway (genioglossus, alae nasi, posterior arytenoids, pharyngeal dilators, sternohyoid, etc.) increases the caliber of the upper airway and diminishes its susceptibility to collapse during inspiration.[16] Contraction of the muscles of the chest wall (e.g., diaphragm, intercostals, abdominals, and neck muscles) transiently reshapes the thoracic geometry, which allows it to generate negative pressure, resulting in inhalation or inspiration.[16] In patients with normal neuromuscular function and dead space fraction, the diaphragm alone can produce adequate ventilation, as evidenced by normal gas exchange during rapid eye movement (REM) sleep when all muscles of respiration, other than the diaphragm, are paralyzed. However, disease states that affect the strength and endurance of respiratory muscles may result in hypoventilation. Although hypoventilation typically arises first during REM sleep for the reason noted above, over time, it may progress to daytime hypercapnia.

A complex array of mechanoreceptors and proprioceptors whose afferents project to respiratory neurons in the brain stem and higher CNS structures provides the respiratory controller with information about the mechanics of breathing and performance of the ventilatory pump.[16] The sensory receptors providing this afferent feedback and the CNS structures that integrate the feedback into a coordinated respiratory response are not perfectly understood. However, mechanoreceptors in the intercostal muscles that sense muscle tension and length (Golgi tendon receptors and spindle organs, respectively) and pressure and flow sensors in the lower (vagal irritant receptors) and upper airway (larynx and mouth) clearly play a role in shaping the neuromuscular response to alterations in the mechanics of breathing.

■ Alterations in Respiratory Muscle Function and Compensatory Mechanisms

Individuals with decreased lung compliance, as seen in either conditions of increased resistive loading such as obesity, or restrictive diseases such as kyphoscoliosis or pulmonary fibrosis, require increased transpulmonary pressures to produce changes in lung volume as compared to individuals with normal compliance.[30] Their work of breathing is increased, putting them at risk for respiratory muscle fatigue and resultant hypercapnia.

A study evaluating patients with restrictive lung physiology secondary to interstitial lung disease (ILD) showed that such patients have a shorter inspiratory time as well as higher respiratory and lower tidal volume compared with matched controls. Additionally, a higher degree of diaphragmatic and intercostal neuronal stimulation was noted; however, evidence for decreased neuromuscular coupling was noted, as seen in reduced mouth occlusion pressure

($P_{0.1}$) compared to diaphragmatic electromyography (EMG) in patients with ILD compared to controls. These findings could be explained by reduced inspiratory muscle strength.[31] Research on subjects with intact neuromuscular function, as well as normal lung and chest wall mechanics, demonstrated that their respiratory pattern was altered as muscles fatigued. Rapid, shallow breathing was adopted by subjects experiencing respiratory muscle and isolated diaphragmatic muscle fatigue.[32]

In obstructive lung disease such as COPD, respiratory pump function is altered due to extrinsic and intrinsic changes occurring as a function of the disease process. Extrinsic changes refer to alterations in chest wall shape, lung volumes, and systemic metabolism, whereas intrinsic factors relate to respiratory muscle fiber size, composition, and muscle metabolism.[33]

COPD is characterized by increased resistance to expiratory flow and increased end-expiratory volume resulting in hyperinflation. Hyperinflation alters the overall shape of the diaphragm and the length and size of muscle fibers due to the increased diameter of chest wall, putting it at a mechanical disadvantage. Patients with COPD often develop a rapid, shallow breathing pattern in the absence of impending respiratory failure in order to reduce work of breathing by limiting tidal volumes and decrease perceived dyspnea.[34] Increased respiratory rate is required to maintain appropriate alveolar ventilation; however, due to the previously described mechanical limitations, respiratory rate augmentation is limited and hypercapnia often ensues.

In an effort to maintain eucapnia and normoxia, increased neuronal stimulation to the diaphragm and accessory muscles arises in COPD; however, diaphragmatic fatigue is uncommon. For example, even in states of increased phrenic nerve stimulation[35] or exhaustive exercise,[36] a decrease in transdiaphragmatic pressure may not be noted. This is likely due to alteration of the skeletal muscle to compensate for a chronically elevated resistive load. Specific alterations to decrease respiratory fatigue include increased mitochondrial activity, increased ATP generation relative to ATP consumption, and a transition from type II fast-twitch to less fatigable type I slow-twitch muscle fibers.[37,38] Despite these adaptive changes, respiratory muscle fatigue may occur. Contractions producing large increases in intra-abdominal pressure, as seen with forced expiration, produce more diaphragmatic fatigue than muscle activation required to generate large increases in negative intrathoracic pressures, such as maximum inspiratory efforts.[39] This can explain the increased incidence in diaphragmatic fatigue in patients with advanced COPD who rely on accessory muscles of respiration to aid in maintenance of alveolar ventilation. Diaphragm fatigue is presumed to result from compromised blood flow to the muscle during the periods of increased intra-abdominal pressure required for expulsive efforts.[39]

■ Effects of Sleep

Chemoreceptor responses to chemical stimuli to breathing are deeply influenced by sleep. O_2 and CO_2 chemosensitivity are depressed during slow-wave and REM sleep. During wakefulness ventilation is largely independent of changes in Pa_{CO_2}: ventilation persists even when Pa_{CO_2} is less than about 30 to 35 mm Hg. Persistence of ventilation in the setting of hypocapnia (the so-called wakefulness drive to breathe) probably represents the effects on medullary neurons of inputs activated by auditory, visual, and tactile stimuli. In contrast, in the sleeping state, the ventilatory response to CO_2 extrapolates to zero ventilation in the hypocapnic range. In fact, apnea occurs when Pa_{CO_2} falls only 4 to 6 mm Hg below waking eucapnic levels. Sleep-related changes in chemosensitivity, therefore, underlie the recurrent periods of apnea and hyperpnea and exaggerated hypercapnia that occur in some patients with diseases of the lung and chest wall.

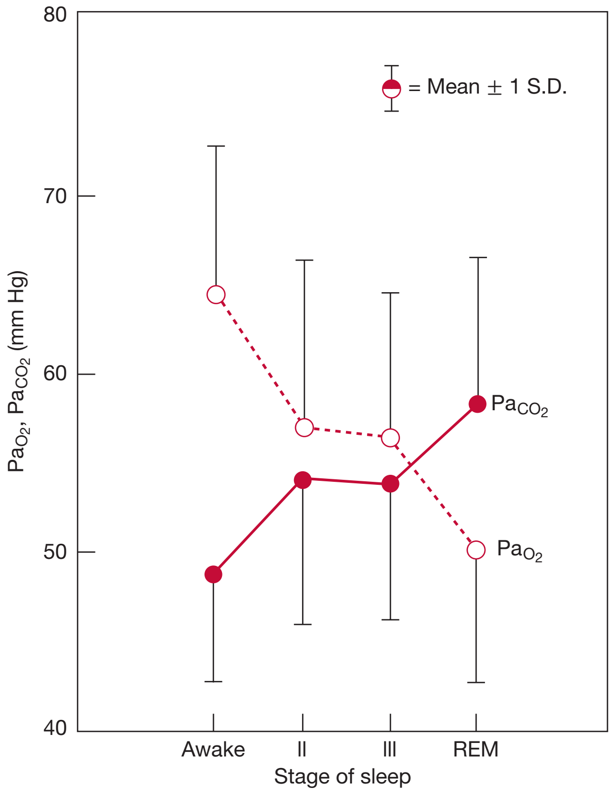

Figure 142-3 Changes in steady-state arterial P_{CO_2} during sleep in eight patients with stable COPD. Note that arterial P_{CO_2} increases and arterial P_{O_2} decreases during sleep. Greatest changes occur during REM sleep. For Pa_{CO_2}, average increase is 10 mm Hg. *(Data from Koo KW, Sax DS, Snider GL. Arterial blood gases and pH during sleep in chronic obstructive pulmonary disease. Am J Med. 1975;58(5):663–670.)*

The increase in respiratory motor activity induced by derangements in respiratory mechanics is also state-dependent—that is, heightened activity in awake subjects is absent in sleeping or anesthetized subjects. REM sleep, in particular, impairs the "load" response and causes collapse of the upper rib cage during inspiration, which adversely affects the level of ventilation as well as its distribution. Descending inhibitory drives to spinal α- and spindle γ-motor neurons in REM sleep cause atonia of all the respiratory muscles except the diaphragm. The diminished or absent load response during sleep explains the exaggerated increases in Pa_{CO_2} that occur during these periods in patients with lung and chest wall disorders. In fact, REM sleep is the period in which Pa_{CO_2} is highest and Pa_{O_2} lowest in patients with stable COPD (Fig. 142-3).

USE OF NONINVASIVE POSITIVE PRESSURE VENTILATION (NIPPV) IN HYPOVENTILATION

NIPPV for hypoventilatory syndromes of any nature rely on the use of home-based portable, battery-capable, and alarm-equipped life-support ventilators. NIV is provided using pressure-cycled ventilatory modes: bilevel pressure support (PS) with spontaneous and timed breaths (bilevel/BPAP S and S/T) or bilevel pressure control (PC). BPAP S/T allows for both patient-triggered (flow or pressure) breaths as well as time-triggered breaths. With PC all breaths are supported.

For BPAP S/T and PC modes, a backup rate is set as well as an inspiratory time (Ti). The inspiratory pressure (IPAP) and expiratory pressure (EPAP) are set and do not vary in PS or PC. Spontaneous/patient-triggered breaths are supported until the patient-generated inspiratory flow reaches a preset decline from its peak which induces ventilator cycling (transition from inspiration to expiration). Timed breaths are supported for the entire preset Ti. Consequently, tidal volume (Vt) will be defined by intrinsically variable respiratory system mechanics (e.g., lung compliance, thoracic recoil) and Ti. This translates into almost minute-to-minute variability in minute ventilation (MV) and, likely, a decrease in ventilation as NMD progresses.

Either PS or PC can be coupled with software modifications designed to provide a steady Vt and MV (volume-assured pressure support or VAPS). Note that VAPS is not a ventilatory mode in itself, but rather, an algorithmic manipulation in which the ventilator can sense real-time instantaneous variations in Vt or MV and bidirectionally adjust the level of pressure support (IPAP–EPAP) within an operator-defined range and rate, to reach a target tidal volume. This "adaptive" feature allows maintenance of a steady or "assured" ventilation and enables automatic compensation or "autotitration" for episodic changes in respiratory mechanics (dynamic lung compliance changes due to position, volume status), sleep stages (REM-related hypoventilation), and changes related to progressive ventilatory compromise inherent to NMD.

The ability to control and set a minimum and maximum inspiratory time (Ti min, Ti max) blurs the line between PS and PC. Initially, the breath is fully supported until Ti min is reached (both spontaneous and timed breaths), but once the breath reaches Ti min the rate of flow decline determines the ultimate duration of inspiration beyond Ti min. If flow has not reached the cycling threshold by Ti max, the ventilator will then cycle, effectively terminating inspiration. This algorithm practically makes the interval between the onset of inspiration and Ti min function as pressure control, and the interval between Ti min to Ti max as pressure support.

Current home ventilators with VAPS features can also autotitrate EPAP (VAPS-AE), mirroring auto-CPAPs and providing effective and variable upper airway stenting in patients with overlapping obstructive sleep apnea and nocturnal alveolar hypoventilation. These features are summarized in Fig. 142-4.

SPECIFIC HYPOVENTILATORY SYNDROMES

The vast majority of clinical conditions leading to hypoventilation can be encompassed into four major groups: neuromuscular or thoracic cage diseases, obesity–hypoventilation, chronic obstructive pulmonary disease, and central hypoventilation.

Neuromuscular Disease

A variety of neuromuscular diseases may be complicated by hypercapnic respiratory failure, as discussed below.

Pathophysiology, Disease Progression, and Diagnosis of Hypercapnic Respiratory Failure in Patients with Neuromuscular Disease

The neuromuscular effector component of the respiratory pump is effectively compromised by a variety of conditions generically known as neuromuscular diseases (NMD). The diverse pathophysiologic mechanisms involved, some unique to each entity, affect ventilation in different ways and degrees, but they all converge in producing pulmonary restriction, decreased forced vital capacity (FVC), normal or elevated FEV_1/FVC, low total lung capacity (TLC) and functional residual capacity (FRC), and decreased inspiratory and expiratory forces (MIP and MEP, respectively). What is also unique about NMD is that patients demonstrate an impaired ability to sigh (i.e., a greater than twofold increase in the tidal volume) because of inspiratory muscle weakness. Inability to sigh decreases lung compliance by interfering with the redistribution of surfactant within the alveolar space. Progressive stiffening of the lung leads to microatelectasis and, ultimately, to lobar atelectasis. In addition, expiratory muscle weakness impairs the cough mechanism and causes retention of secretions, contributing to regional atelectasis and reduced FRC and ventilatory reserve.

NMD includes neuropathic and myopathic disorders, such as amyotrophic lateral sclerosis (ALS), spinal muscular atrophy (SMA), muscular dystrophies (MD), myasthenia gravis, poliomyelitis including postpolio syndrome, and glycogen storage and mitochondrial diseases. These conditions affect various components of the nervous system (afferent and efferent conduction, neuromuscular junction, and muscles), potentially leading to chronic hypercapnic respiratory failure.

Congenital or acquired abnormalities of the thoracic cage (e.g., kyphoscoliosis) impair the mechanical coupling generated by muscle contraction and make the thoracic cage–lung apparatus ineffective. These disorders physiologically mirror NMD. The elastic work of breathing is markedly increased. In addition, the mechanical action of the respiratory muscles may be impaired by changes in configuration of the bony structures on which the respiratory

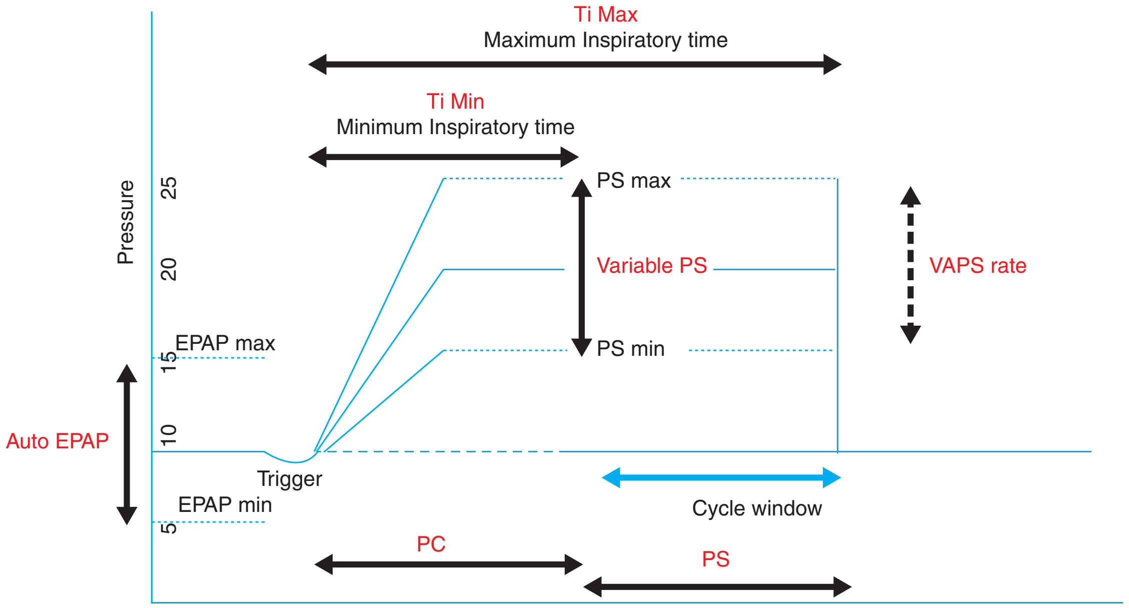

Figure 142-4 Volume-assured pressure support (VAPS). See text for explanation.

muscles insert. Ventilation–perfusion mismatch and increases in the alveolar–arterial O_2 gradient are common. As expected in patients with diminished respiratory compliance, subjects with kyphoscoliosis breathe rapidly and shallowly. The tendency to develop CO_2 retention is a function of the severity of the restrictive process in kyphoscoliosis, as reflected in the Cobb angles, and is predicted separately for the magnitude of scoliosis and kyphosis.

Hypercapnic respiratory failure tends to develop late in life, even if the severity of the spinal deformity has not changed since childhood—that is, stability of the Cobb angles of kyphosis and scoliosis does not preclude development of hypercapnic respiratory failure. It is not clear why respiratory failure ensues late in life. However, several possibilities may be considered. Aging adversely affects compliance of the chest wall, leading to an increase in the elastic work of breathing. In addition, aging diminishes respiratory muscle strength. Finally, chemosensitivity to O_2 and CO_2 declines with advancing age, and it seems likely that the subject's ability to compensate for derangements in blood-gas tensions is progressively impaired.

Patients with ALS, SMA, and some muscular dystrophies tend to develop rapidly progressive respiratory failure, whereas patients with myopathies have a slower, chronic decline in respiratory function. Elevated serum bicarbonate levels greater than 28 mEq/L or elevated arterial carbon dioxide (Pa_{CO_2}) levels above 45 mm Hg tend to be late manifestations of hypoventilation in patients with NMD and no other underlying pulmonary insufficiency.

Hypoventilation generally occurs as a result of inspiratory muscle weakness, with nocturnal hypoventilation being the heralding sign of overt respiratory failure. Since ventilation depends almost exclusively on the diaphragm during REM sleep, transient REM-related hypercapnia may be seen early in NMD, often before sustained diurnal hypercapnia occurs. Polysomnography (PSG) with end-tidal CO_2 ($ETCO_2$) or transcutaneous carbon dioxide monitoring ($PtcCO_2$) , both surrogate markers for Pa_{CO_2}, is useful in diagnosing nocturnal alveolar hypoventilation (Fig. 142-5).

Nocturnal hypoventilation can be diagnosed if Pa_{CO_2} (or a surrogate) is >55 mm Hg during sleep for ≥ 10 min, or Pa_{CO_2} (or its surrogate) increases ≥ 10 mm Hg from wake levels for ≥ 10 min.[40] These definitions are rather arbitrary. Additionally, patients with hypoventilation may also have concomitant OSA that manifests with symptoms of snoring, choking, gasping, witnessed apneas, and daytime somnolence. Important to note is that treatment should include a combination of ventilatory support as well as upper airway stabilization, as repetitive obstructive apneas, if present, can exacerbate underlying nocturnal hypercapnia.

ALS-related respiratory failure represents as good model for explaining how ventilatory failure presents and progresses in NMD and how ventilatory support can be provided. Patients newly diagnosed with ALS should undergo baseline pulmonary testing, including spirometry (particularly vital capacity) and periodic retesting for disease progression. Once FVC is $<80\%$ predicted, negative inspiratory force <60 mm H_2O,[41] peak cough expiratory flow <270 L/min,[42] or nocturnal hypoxia is detected, an evaluation for nocturnal hypoventilation should be considered, even in absence of symptoms. The best indicators of a tendency to develop CO_2 retention in patients with neuromuscular disease are reductions in inspiratory muscle strength (Pi_{max}) and FVC. Reductions in Pi_{max} and FVC to $<30\%$ and 25% of predicted, respectively, are associated with CO_2 retention. Overt symptoms of hypercapnia include daytime somnolence, morning headaches, and decreased cognition or attention.

Treatment of Hypoventilation

Treatment of hypoventilation in the setting of neuromuscular disease entails consideration of a variety of mechanical ventilation modalities, as well as adjunctive measures.

Noninvasive Positive Pressure Ventilation (NIPPV) ALS is the NMD for which NIPPV is most commonly prescribed; however, a consensus for timing of institution of NIPPV in this patient population does not

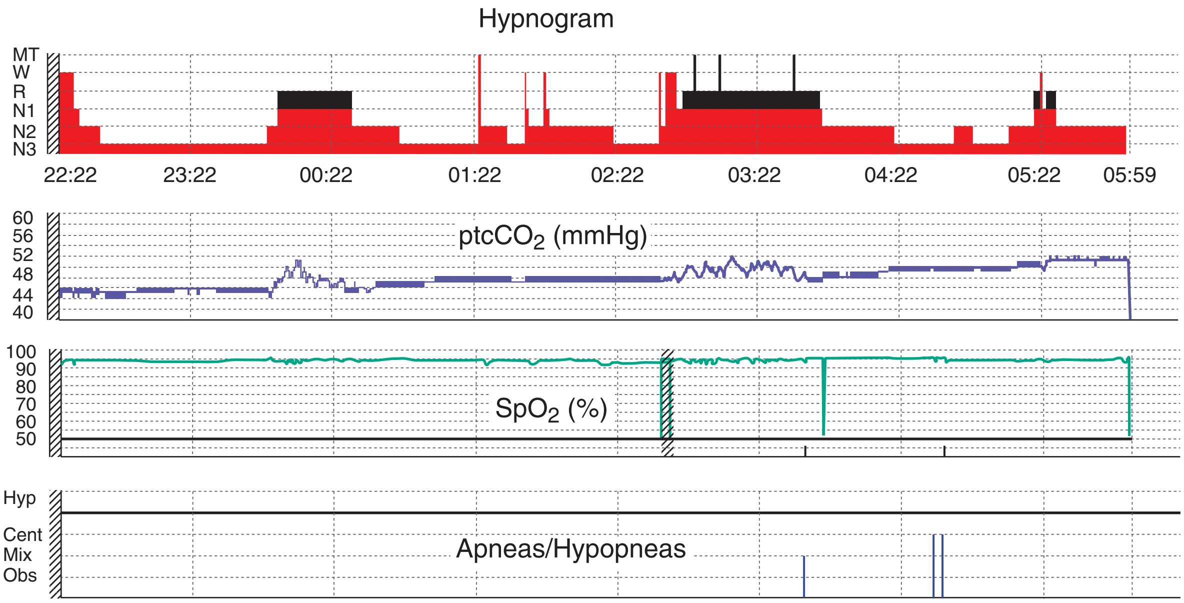

Figure 142-5 Polysomnography synopsis from a 67-year-old non-ventilated male patient with spinal-onset ALS. The figure depicts four tracings representing hypnogram, transcutaneous capnometry, pulse oximetry, and graphical presentation of apneas or hypopneas *(from top to bottom)*. Whereas capnometry shows hypercapnia, which begins during REM and persists during the last third of the night, peripheral oxygen saturation is normal throughout the entire recording. ALS, amyotrophic lateral sclerosis; Cent/Mix/Obs, central/mixed/obstructive apneas; Hyp, hypopneas; N1–N3, non-REM sleep stages; ptcCO_2, transcutaneous carbon dioxide tension; REM/R, rapid eye movement sleep; SpO_2, peripheral oxygen saturation; W, wake. *(Nature and Science of Sleep. 2019:11 97–111. Originally published by and used with permission from Dove Medical Press Ltd.)*

exist.[41] Conflicting data exist regarding the value for FVC at which NIPPV should be initiated; the general consensus recommends starting nocturnal NIPPV once FVC drops to <50% of predicted;[42] however, some investigators have found that initiation of NIPPV once FVC is <75% of predicted reduces mortality in ALS patients.[43] What is clear is that NIPPV consistently prolongs survival in ALS (Fig. 142-6).

In addition to FVC decline, initiation of nocturnal ventilatory support should be considered once one of the following criteria are met: maximal inspiratory pressure (MIP) ≤60 cm H_2O or sniff nasal pressure <40 cm H_2O, or overnight oxyhemoglobin desaturation below 88% for over 5 min.[44]

NIPPV is recommended for patients with ALS in the absence of significant bulbar symptoms, as this group has been demonstrated to have improved morbidity and mortality with NIPPV therapy.[45,46] Nocturnal hypoventilation is often the heralding sign of overt respiratory failure; therefore, ventilatory support should be initiated at the first sign of diurnal hypercapnia.

NIPPV is acceptable in patients without bulbar dysfunction, who are able to protect their airway from aspiration of oral secretions, and whose respiratory muscles are able to sustain the effort of respiration without continuous support. Additionally, NIPPV is appropriate for patients who wish to avoid early tracheostomy.

As NMD progresses and respiratory muscles are no longer able to generate and sustain consistent and effective inspiratory flow, the level of nocturnal NIPPV can be progressively modified to match the patient's needs by taking advantage of proprietary-brand algorithms embedded in Respiratory Assist Devices (RADs) and home ventilators. Such modifications may be effected by cleverly modifying ventilatory parameters and pressure-cycled modes—for example, by transitioning to VAPS pressure-control or lengthening Ti minimum to support the entirety of the breath while keeping the patient on pressure-support or bilevel VAPS (i.e., Ti min = Ti max) and making breaths the same as pressure control breaths.

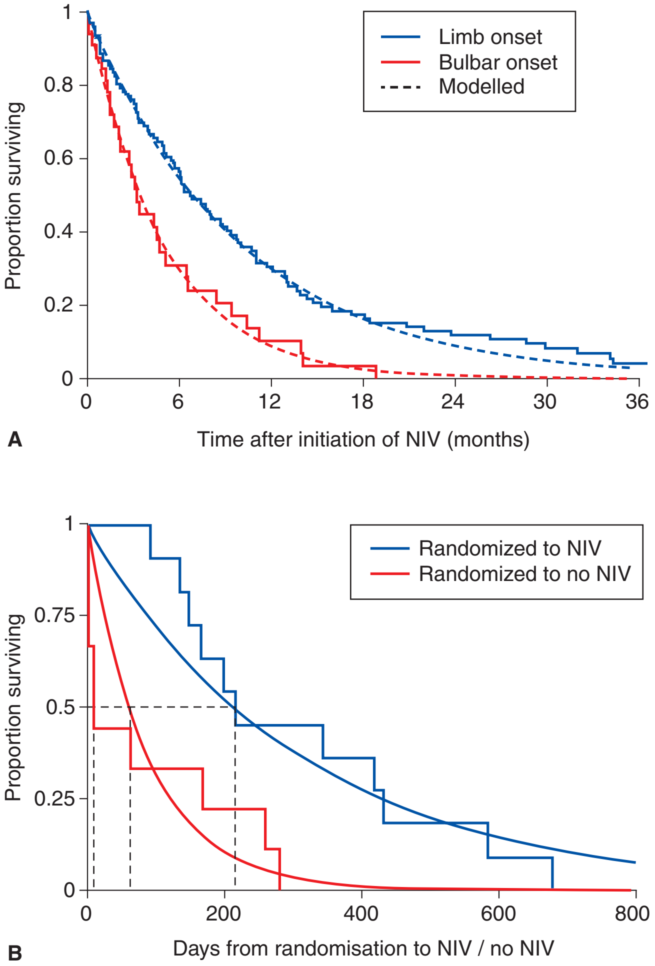

Figure 142-6 **A.** Limb-onset ALS has a better overall survival compared with bulbar-onset. **B.** Institution of NIV in ALS results is a significantly delayed death. *(Reproduced with permission from Knibb JA, Keren N, Kulka A, et al. A clinical tool for predicting survival in ALS. J Neurol Neurosurg Psychiatry. 2016;87(12):1361–1367.)*

Patients with NMD are typically "air hungry" and are often unable to generate an inspiratory flow capable of triggering the ventilator. Effective ventilation and perceived comfort require longer inspiratory times and ventilator-triggered breaths. PC ventilation is sometimes preferred since it assures a Ti for any given level of PS as spontaneous breaths become more ineffective with disease progression (diminished inspiratory effort and inability to sustain flow due to inspiratory muscle weakness).

In NMD, mean pressure support and IPAP are lower in the VAPS algorithm compared with pressure support (PS) for any given tidal volume,[47–49] although studies differ in comparability of respiratory rate and tidal volume. Investigators have reported preserved minute ventilation in both VAPS and PS groups;[49] however, VAPS appears to generate greater, more consistent tidal volumes and lower respiratory rates compared to the rapid shallow breathing seen with PS. This may be related to decreasing tidal volumes when fixed PS settings are used as NMD progresses, resulting in increased rapid shallow breathing. Tidal volume depends on lung mechanics and the ability to sustain and inspiratory flow; the latter decreases as respiratory muscle weakness progresses. The differences in respiratory rate and tidal volume between the VAPS and PS are largely due to the fact that in ALS, breath triggering remains relatively preserved; however, breath cycling decreases with increasing respiratory muscle weakness.[49] Therefore, it is imperative that these patients are treated with a ventilator mode or algorithm that allows for set inspiratory time in order to support an entire breath independently from effort and flow-cycling as the disease progresses.

VAPS and appropriately monitored PS are largely comparable with regard to diurnal oxygenation, CO_2 levels[48] and patient compliance,[49] although some have reported a patient preference of VAPS over PS.[47] A significant benefit of using VAPS is that it can automatically account and compensate for unintentional air leak and adjust pressure support to maintain target tidal volume. This feature can be used to overcome large leaks when VAPS is used invasively in tracheostomy patients the cuff is deflated or an uncuffed tracheostomy tube is placed, thus providing continued ventilatory support while allowing for patient phonation and decreasing local tracheal complications.

Regardless of the ventilatory mode chosen mode, initial settings are generally a minimum tidal volume of 8 cc/kg predicted body weight. Additionally, a highly sensitive trigger should be set to allow for patient-initiated breaths in advanced NMD. Lastly, for flow-cycled breaths based on percentage of peak flow, values must be very low (in the 8%–15% range) to allow for ventilator support through the majority of the breath[48] to ensure adequate respiratory muscle rest. This is confirmed by a decrease in diaphragmatic electromyographic (EMG) activity during sleep, or by an increased inspiratory transpulmonary pressures measured using an intraesophageal balloon in controlled sleep laboratory conditions. Modern home ventilators are able to analyze and report percentage of triggered breaths allowing fine tuning to decrease respiratory muscle load during sleep. As disease progresses, it is common to transition from flow-cycled breaths to Ti-cycled breaths in order to maintain ventilation in the face of weakening inspiratory muscles. Longer Ti equates to larger tidal volumes and recruitment of microatelectatic regions of the lung. Lastly, setting an appropriate back up rate to deliver the majority of breaths is necessary to allow for respiratory muscle rest.

Tracheostomy For patients with bulbar-onset ALS who are severely symptomatic, are unable to clear secretions, and desire to live as long as possible, tracheostomy and invasive ventilatory support are the mainstays of treatment. Important to consider are the potential repercussions of tracheostomy placement, as it complicates care and may require hiring of skilled caretakers or transition to a long-term care facility. The need for continuous, 24-h ventilatory support does not necessarily translate into tracheostomy, as studies have demonstrated success with long-term, continuous use of NIPPV in the absence of significant bulbar symptoms.[45] However, interface (mask)-related skin abrasions and pressure damage, along with altered respiratory secretion clearance, eventually results in transitioning to tracheostomy for continued ventilatory support.

Adjunctive Treatments Coughing helps to mobilize and clear secretions from the airway, thus decreasing risk of atelectasis and subsequent restrictive pulmonary physiology, as well as pneumonia. Coughing requires coordinated activation of a number of muscles to be successful. First, the patient must be able to take in a sufficiently large volume of air and then close the glottis briefly, thereby raising intrathoracic pressure. Thereafter, opening the glottis in conjunction with contraction of abdominal muscles results in forceful expulsion of air, leading to a cough.[50] All of these steps can be compromised in patients with advanced neuromuscular disease, especially if bulbar dysfunction is present, leading to poor secretion clearance and its negative sequelae. Secretion expectoration with coughing requires a minimum peak cough flow of 180 L/min, as measured using a handheld flow meter.[51] If a patient is unable to produce this flow, adjunctive treatments should be implemented in the form of cough assist devices, which can be considered in two categories: those that assist with cough augmentation, and those that facilitate secretion mobilization.

Cough augmentation can be achieved through improvement in exhalation, as well as through support of inhalation. Exhalation support can be achieved via manually assisted cough (MAC) techniques, including costophrenic compression or Heimlich-type abdominal thrusts, which displace the diaphragm up, leading to air expulsion.[52]

In addition, negative pressure can be applied via facemask—a technique called *exsufflation*. Assisted inspiration allows for a patient with NMD to take in an increased volume of air on inspiration, allowing more air to be exhaled and raising peak cough flow in patients with intact glottic function. Assisted inspiration can be used through delivery of breaths via noninvasive ventilation or intermittent positive pressure breathing through the use of a bag-valve mask.[52] These delivery systems can either deliver a single breath or multiple, stacked breaths.

Mechanical insufflation–exsufflation (MI-E) devices function via facemask or are attached to tracheostomy tube and provide positive pressure ventilation, followed by a rapid switch to negative pressure, thereby generating a cough.[53] Modes of assisted inspiration can also be combined with manually assisted cough techniques. MI-E, when used in conjunction with MAC, appears to produce the greatest peak cough flow when compared to MI-E alone or assisted inspiration followed by MAC.[54] In a small pilot study evaluating traditional tracheal suctioning compared with MI-E via a cuffed tracheostomy tube with the cuff deflated, investigators found that MI-E was more effective and better tolerated.[55] To our knowledge, there have been no long-term studies regarding morbidity or mortality outcomes specifically for MI-E devices.[56]

Secretion mobilization techniques include manual chest wall percussion, high-frequency chest wall oscillations (HFCWO), high-frequency chest wall compression (HFCWC), and intrapulmonary percussive ventilation (IPV). Manual percussion, with or without postural drainage, involves percussing a patient's back to loosen and mobilize secretions. HFCWO and HFCWC involve compression of the chest via a pneumatic vest encasing the thorax. The vest inflates and transmits high frequency oscillations to the chest, producing oscillations in airflow and mobilizing secretions. HFWCO repeatedly inflates and deflates, whereas HFWCC tonically inflates and provides superimposed oscillations.[57] IPV involves intermittent positive pressure breathing with high-frequency bursts of airflow that provide internal percussion to the bronchial tree and promote secretion clearance.[52]

OBESITY HYPOVENTILATION SYNDROME (OHS)

Obesity hypoventilation syndrome is a common and important entity, a hallmark of which is hypercapnia. In addition to the discussion below, the reader is referred to Chapter 99, Sleep-Related Hypoventilation Syndromes.

Diagnosis and Pathophysiology

Obesity imposes a mechanical stress and added load on the respiratory system by altering lung mechanics and the work of breathing. The mass loads applied to the thorax and abdomen by excess adipose tissue decrease chest wall compliance and end-expiratory lung volumes, resulting in increases in the elastic and resistive work of breathing. Furthermore, by diminishing airway caliber, obesity predisposes to premature airway closure and atelectasis. This results in areas with low ventilation–perfusion ratios (V/Q) resulting in an increased alveolar–arterial O_2 gradient and arterial hypoxemia.

The excessive body mass also results in increased CO_2 production and O_2 consumption. Increases in metabolism may be two to three times normal in morbidly obese subjects.[58] For example, a doubling in CO_2 production requires a doubling in alveolar ventilation to maintain eucapnia. These metabolic changes require significant increases in minute and alveolar ventilation to maintain eucapnia, dramatically increasing ventilatory demands in a mechanically overloaded system, with inherently diminished ventilatory reserve. Finally, arterial hypoxemia, which is common, induces a further increase in ventilation. Given these stresses, the maintenance of normal blood–gas tensions requires a considerable increase in respiratory motor output and the work of breathing. Increased work of breathing appears to explain the common occurrence of dyspnea in the morbidly obese person.

Not all morbidly obese subjects develop hypercapnic respiratory failure, however. Although body weight alone does not predict the development of hypercapnia, approximately 30% of severely obese subjects with a body mass index (BMI) >35 kg/m^2, and almost 50% with a BMI ≥ 50 kg/m^2, have unexplained daytime hypercapnia. Observations of eucapnic and hypercapnic obese subjects demonstrate that eucapnic subjects have greater increases in diaphragm electrical activity with increases in CO_2 than do hypercapnic subjects. Obese subjects with hypercapnic respiratory failure may have impaired chemosensitivity to hypercapnia and hypoxemia. The sustained gas exchange abnormalities often result in a subset of obese, hypercapnic subjects developing polycythemia, pulmonary hypertension, and cor pulmonale (Fig. 142-7).

The diagnosis of obesity hypoventilation syndrome (OHS) is made in a patient who has a body mass index (BMI) ≥ 30 kg/m^2 in conjunction with daytime hypercapnia, with $Pa_{CO_2} > 45$ mm Hg, in the absence of other causes of alveolar hypoventilation.[59] OSA is present in the vast majority of patients with OHS, but it is not a requisite to make the diagnosis.

Sleep-related hypoventilation is defined as an increase in $PaCO_2$ or a surrogate marker (e.g., $ETCO_2$, $PtcCO_2$) of >10 mm Hg during sleep (compared with wake supine levels) and to >50 mm Hg for >10 min.[40] This is a rather arbitrary definition, with clinical outcomes more precisely described in the pediatric population. The clinical implications

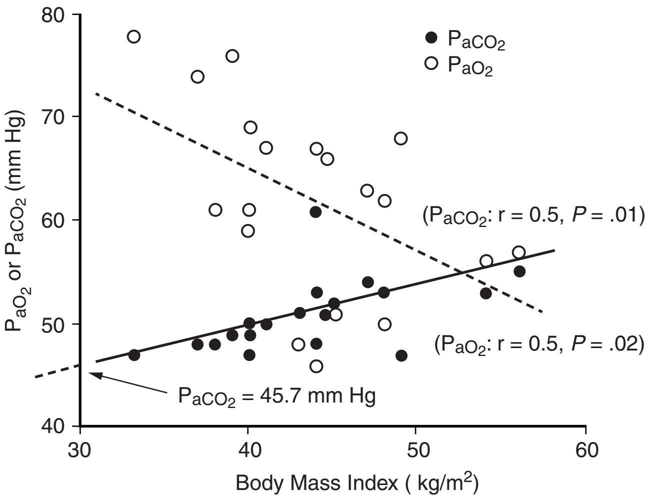

Figure 142-7 As BMI increases, so do gas exchange abnormalities: Pa_{CO_2} steadily increases as Pa_{O_2} decreases for any given BMI above 30 kg/m^2. *(Data from Mokhlesi B, Tulaimat A, Faibussowitsch I, et al. Obesity hypoventilation syndrome: prevalence and predictors in patients with obstructive sleep apnea. Sleep Breath. 2007;11(2):117–124.)*

of fluctuating Pa_{CO_2} during sleep, and whether a variation of 10 mm Hg is more clinically significant than a change of 5 or 15 mm Hg, is speculative at best. If CO_2 fluctuations do not result in hypercapnia during wakefulness, then it is unclear that, aside from heralding diurnal hypercarbia, they have any true clinical significance.

Consideration for OHS should be given to obese patients who are at an elevated risk for OSA, as defined by at least an intermediate pretest probability based on validated-standardized clinical screening tools and questionnaires, a serum bicarbonate ≥27 mmol/L, or significant oxyhemoglobin desaturations unexplained by obstructive events (nonobstructive desaturations) on overnight pulse oximetry.[60,61] A good patient history, pulmonary function tests, and, possibly, a computed tomography (CT) scan of the chest should be obtained to rule out other causes of hypoventilation. Pulmonary function tests may be normal, but they typically demonstrate mild to moderate restrictive physiology. Chest CT should not show evidence of significant parenchymal or pleural disease, thoracic cage malformation, or other causes of restriction.

The mechanism by which OHS leads to chronic hypercapnic respiratory failure is incompletely understood. Various theories include altered chemosensitivity to hypercapnia and hypoxia; leptin resistance; abnormal respiratory mechanics, such as decreased lung compliance and increased restrictive physiology; increased work of breathing leading to muscle fatigue; and obstructive apneas. Fewer than one-third of patients who are obese develop chronic hypercapnia, arguing against altered respiratory mechanics in isolation as the main cause of hypercapnia.[60]

Typically, hypoventilation first develops during REM sleep. This is due to REM-induced paralysis of the accessory muscles of respiration, in conjunction with decreased diaphragmatic excursion from abdominal adiposity and exaggerated upward displacement of the diaphragm when supine. Furthermore, respiratory muscles fatigue due to the increased work of breathing from body habitus, as well as need for increased respiratory rate in response to decreased functional vital capacity and increased resistance seen in obesity,[62] leading to CO_2 retention. As a response to cyclically elevated CO_2 levels, over time, central chemoreceptors develop decreased CO_2 sensitivity,[63] leading to continuous hypercapnia. Additionally, patients with OHS tend to have increased leptin levels and leptin resistance, thus reducing respiratory drive, as leptin is a potent respiratory stimulant.[63]

■ OHS Phenotypes and Their Management

Most patients diagnosed with OHS demonstrate some sleep-related breathing disturbance; however different phenotypes involve varying sleep disturbances. OSA encompasses approximately 90% of the sleep-disordered breathing in OHS; however, 10% have sleep-related hypoventilation in the absence of obstructive events.[64]

Approximately 70% of patients with OHS have severe OSA, defined as an apnea-hypopnea index (AHI)—the average of obstructive, hypopneic, and central events per hour of sleep—of ≥30 events/h; 30% have mild OSA (an AHI of 5–14 events/h) or moderate OSA (an AHI of 15–29 events/h) or a lack of significant obstructive or hypopnea events with continued nocturnal hypoventilation.[64] This distinction leads to differing modes of treatment based on the predominant underlying disturbed breathing pattern during sleep.

OHS with Severe Obstructive Sleep Apnea

Patients with OHS with an AHI >30 tend to be younger and male and to have higher BMI and daytime sleepiness scores compared with patients with OHS without severe OSA. Surprisingly, this phenotype also tends to have less cardiovascular morbidity and mortality.[65] Oxyhemoglobin desaturations are likely to be more pronounced and slower to resolve, due to reduced functional vital capacity in these patients. Additionally, obstructions are longer in duration, leading to hypercapnia. Computer models demonstrate that when periods of apnea are more than three times as long as the terminating hyperventilation, hypercapnia may ensue.[66] By solely decreasing obstructive events, many of these patients are able to achieve eucapnia. Consequently, a large percentage of these patients can be successfully treated with CPAP alone.

OHS without Severe Sleep Apnea

In patients with OHS who lack evidence of severe sleep apnea, but who still demonstrate nocturnal hypoventilation, CPAP is usually an ineffective treatment. This subset of patients often requires NIPPV. A study demonstrated significant reductions in Pa_{CO_2}, serum bicarbonate, and Epworth Sleepiness Scores (ESS) in patients with OHS treated with VAPS compared with lifestyle modification alone.[67] All subjects included were required to use VAPS ≥4 h per day. Additionally, time to emergency department visit was longer in patients treated with NIPPV compared with controls.[68]

Malignant OHS

Malignant obesity–hypoventilation syndrome has been described in a small, observational study as a subset of patients who meet criteria for OHS, whose BMI >40 kg/m^2, and who are admitted to an ICU with evidence of multisystem organ dysfunction.[69] The majority of patients had evidence of left ventricular hypertrophy, left ventricular diastolic dysfunction, and pulmonary hypertension. Since these patients commonly have some degree of pulmonary hypertension, BPAP is the treatment modality of choice, as NIPPV has been shown to impart a positive effect on cardiac structure and function.[70] The American Thoracic Society recommends that patients with OHS hospitalized with respiratory failure be started on NIV treatment during the hospitalization, and that NIV be continued upon discharge. Plans should be undertaken for formal polysomnography and ventilator titration within 3 months of discharge.[61]

Providing ventilatory support (mechanical ventilation, both invasive and noninvasive) to patients with OHS and severe pulmonary hypertension or right ventricular dysfunction, can be challenging at times. Positive pressure ventilation may result in increased right ventricular afterload and acute right ventricular failure and complicate already taxing volume management. NIPPV may also result in worsened V/Q mismatch, producing further hypoxemia despite increases in minute ventilation.

Natural Progression of OHS and Diagnosis of Hypercapnic Respiratory Failure

The diagnosis of OHS often lags behind patient complications from the disease. In fact, patients who are ultimately diagnosed with OHS tend to have increased health care utilization and ICU visits up to 5 years before their diagnosis compared with BMI-matched counterparts without hypoventilation. In order to capture patients at an earlier phase of their disease process, investigators have recommended evaluating base excess in addition to serum bicarbonate levels.[71] Patients with a base excess >2 mmol/L and normal serum bicarbonate level responded to hypercarbic and hypoxic insults more similarly to patients with OHS, raising the concern that OHS may represent a spectrum of disease. Also, patients with OHS are more likely to develop pulmonary hypertension[72] and resultant cor pulmonale compared to BMI-matched patients with OSA alone.[73]

Mortality is elevated for patients with OHS compared with BMI-matched patients with OSA. In one study, a 2-year all-cause mortality in previously hospitalized patients with OSA of 23% was reported, compared with 9% in previously hospitalized patients with simple obesity.[74] Of note, hypercarbia was defined as $Pa_{CO_2} \geq 43$ mm Hg, and the majority of patients with OHS were not discharged with CPAP or NIV treatment. Additionally, in an observational study of patients with OHS who were admitted to the hospital with acute-on-chronic hypercapnic respiratory failure, a 1-year mortality of 18% was reported[75] (Fig. 142-8).

Treatment of OHS: Phenotypic Considerations in NIPPV and Other Forms of Therapy

The clinical management of OHS requires an understanding of how different phenotypes respond to therapy; indeed, different modes of NIPPV can be equally effective. Furthermore, escalation of therapy is not always required to achieve eucapnia. A subset of patients may benefit from additional therapeutic interventions that either facilitate a safe mode of ventilatory support (e.g., tracheostomy) or provide additional clinical benefits when combined with NIPPV.

NIPPV in Low-AHI and Malignant OHS

Noninvasive positive pressure ventilation is a cornerstone of treatment for patients with OHS. The majority of patients can be treated with CPAP; however, in malignant OHS and low AHI groups, bilevel PS, with or without VAPS, should be first-line therapy. For patients who are started on CPAP, but who demonstrate continued hypercarbia three months after starting therapy, despite adequate CPAP settings and patient adherence, NIPPV should be transitioned to bilevel PAP (PS, S or S/T) or VAPS-AE (see “Use of Noninvasive Positive Pressure Ventilation (NIPPV) in Hypoventilation,” above, for details).

These patients often require high levels of PS to overcome the mass load and mechanical stress that overweight exerts over the respiratory system. In addition, recumbency during sleep displaces the abdominal contents rostrally, resulting in ineffective diaphragmatic contraction and basilar atelectasis. For this driving force (PS) to be effectively and homogenously applied across the lungs, a prolonged inspiratory time (Ti) is often needed. A short Ti is likely to result in preferential overdistension of viable, non-atelectatic lung segments (in nondependent apical areas). In contrast, a longer Ti will allow progressive recruitment of atelectatic and microatelectatic segments, resulting in a homogenous distribution of Vt and optimized V/Q.

Studies evaluating modes of ventilation have historically not distinguished between phenotypes and their response to specific modes of mechanical ventilation.

For the majority of patients with the high AHI phenotype of OHS, treatment with CPAP alone resolves apneas and hypoventilation. Average CPAP settings for this group are expiratory positive airway pressures of 12 to 14 cm H_2O with treatment for more than 4.5 h per day.[76] Pa_{CO_2} levels should be reassessed after 2 to 3 months of CPAP adherence to ensure resolution of hypercapnia. If, despite this treatment, Pa_{CO_2} remains elevated (≥45 mm Hg), the patient should be transitioned to noninvasive ventilation with use of bilevel PAP. One investigation demonstrated that patients with OHS whose pretreatment Pa_{CO_2} was >62 mm Hg had more than an eightfold increased risk of persistent ventilatory failure compared with those with a $Pa_{CO_2} \leq 50$ mm Hg, despite treatment with CPAP.[77]

When patients with high AHI–OHS are compared with patients with “lower” AHI–OHS with regard to treatment with CPAP versus NIPPV versus lifestyle modification, NIPPV has been found to significantly reduce Pa_{CO_2} levels compared with the other interventions. However, no significant difference has been observed between serum bicarbonate reduction with CPAP (at mean airway pressure of 11 cm H_2O) compared with NIPPV (average bilevel ST: IPAP 20 cm H_2O, EPAP 8 cm H_2O, rate 14). Both CPAP and NIPPV have been demonstrated to be superior in reducing serum bicarbonate when compared with lifestyle modifications alone.[64]

In patients requiring NIPPV support, AVAPS versus BPAP S/T modes of ventilation have been shown to have similar degrees of patient adherence and to produce equivalent reductions in Pa_{CO_2}. Improvements in daytime sleepiness and quality of life metrics also are similar between the groups.[78,79] The AVAPS-AE algorithm produces lower respiratory rates.[79] Additionally, increased tidal volume, IPAP, and total ventilation have been reported with the AVAPS

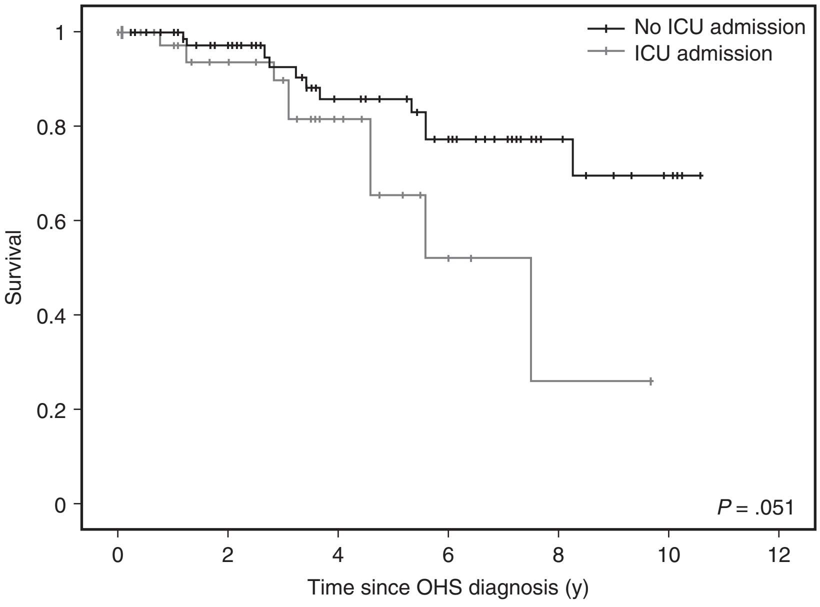

Figure 142-8 Survival of patients with OHS is significantly diminished if the initial diagnosis coincides with admission to ICU with acute hypoxemic respiratory failure. This highlights the importance of early recognition and treatment of this syndrome. *(Reproduced with permission from Chebib N, Nesme P, Freymond N, et al. Acute Respiratory Failure in Obesity-Hypoventilation Syndrome Managed in the ICU. Respir Care. 2019;64(12):1545–1554.)*

algorithm compared with BPAP S/T alone;[80] however, worsened objective and subjective sleep quality were noted with AVAPS compared to S/T, despite improved values for $PtcCO_2$.

Additional studies comparing BPAP with AVAPS to BPAP S/T modes are needed to determine which modality is best tolerated, produces the greatest reductions in CO_2 and mortality, and yields the largest improvement in quality of life. At present, both BPAP with AVAPS and BPAP S/T modes are considered appropriate for use in patients with OHS, given the fact that OHS is not a progressive disease. Therefore, with appropriately titrated EPAP, pressure support, and backup rate settings, adequate minute ventilation can be reliably achieved without the addition of the AVAPS algorithm.

When choosing ventilatory settings for patients with OHS it is important to realize that high levels of pressure support (e.g., in the range of 12–25 cm H_2O) will likely be needed to overcome increased chest wall resistance. The goal for tidal volume is 8 to 10 mL/kg of ideal body weight. EPAP should be initiated at 4 to 8 cm H_2O, but if AVAPS-AE algorithm is used, the level of EPAP will depend on a variety of patient factors. As with patients with neuromuscular disease, patients with OHS benefit from a longer inspiratory time in order to recruit atelectatic regions of lung. We recommend a Ti of 1.2 to 1.6 s in the absence of any obstructive lung disease. Also, to allow for maximal recruitment and to minimize risk of overdistention of non-atelectatic lung, the rise time should be between 400 and 600 ms. If Ti or rise time is too short, patients are put at risk for volutrauma, as the inflation volume is delivered over a short period of time and may over-distend non-atelectatic lung, rather than recruit atelectatic regions.

Tracheostomy

Patients may be intolerant of NIPPV due to discomfort, high pressure requirements needed to overcome obstruction or to provide adequate ventilation, an inability to grasp the severity of illness, or reticence to comply with recommended therapy. Oftentimes, these patients are hospitalized due to malignant OHS and right heart failure. In these patients, tracheostomy should be considered for facilitation of adherence to treatment, to provide a stable airway in lieu of need for intubation, and, often, to serve as a therapeutic bridge that allows safe ventilation if bariatric weight loss surgery is pursued.

Bariatric Surgery

Based on expert opinion by the American Thoracic Society, sustained weight reduction of 25% to 30% of actual body weight is required for resolution of hypoventilation. Bariatric surgery is the most effective and durable manner to accomplish this weight loss, since lifestyle interventions alone only yield an average weight loss of 10 to 12 kg.[81] In one study, statistically significant weight reduction at 3 months was noted when an intensive nutrition program was combined with NIPPV compared with NIPPV alone; however, the effect was lost at 12 months.[82] Bariatric surgery has been shown to produce significant weight loss over the first year following surgery, leading to improvements in hypoxemia and restrictive pulmonary physiology.[83] Patients followed 5 years after bariatric surgery may demonstrate normalization of Pa_{CO_2} and Pa_{O_2}.[84]

Oxygen Therapy

In stable patients with OHS without daytime hypoxia, oxygen therapy has been shown to acutely decrease minute ventilation through decreased tidal volume, resulting in worsening hypercapnia.[85,86] However, when used long-term and titrated to an awake pulse oximetry value of 88% to 92%, oxygen therapy has been shown to increase compensatory metabolic alkalosis.[87,88] As a result, hyperoxia should be avoided in this patient population, and goal oxygen levels measured with pulse oximetry should be between 88% and 92%.

Medications

Multiple medications have been considered as adjunctive treatments of OHS on the basis of respiratory stimulation. Data do not support the routine use of these medications in treatment of OHS.[89,90] The authors recommend against the use of respiratory stimulants outside clinical trials.

Congenital Central Hypoventilation Syndrome

Another important disorder characterized by hypoventilation and hypercapnia is the congenital central hypoventilation syndrome, diagnosis and management of which is discussed below.

Diagnosis and Pathophysiology

Congenital Central Hypoventilation Syndrome (CCHS) is colloquially known as "Ondine's Curse," based on the fable of a jilted water nymph, Ondine, who cursed her unfaithful mortal lover with the ability to breathe only when awake.[91] Scientifically, CCHS is defined as alveolar hypoventilation due to a failure of automatic control of ventilation by the central nervous system which is unrelated to pulmonary, cardiovascular, neurologic, or muscular anomalies.[92,93] Hypoventilation occurs predominantly during sleep; however up to one-third of patients will require ventilatory support 24 h per day.[94] Decreased tidal volume with maintained respiratory rate, impaired ventilatory response to hypercapnia and hypoxia, and absent arousal response to these insults result in excess mortality in untreated CCHS.[95]

A polyalanine expansion mutation in the paired-like homeobox 2B (*PHOX2B*) gene on chromosome 4p12 is found in 90% of patients diagnosed with CCHS.[96] *PHOX2B* is predominantly expressed in the RTN, which is the primary area of chemosensitivity in the CNS. Its inheritance pattern is autosomal dominant; however, de novo mutations account for 90% of cases.[93] The majority of cases are diagnosed in the neonatal period; however, depending on the *PHOX2B* genotype, symptoms may become evident after infancy, which is termed late-onset CCHS (LO-CCHS). Increased polyalanine repeat expansions in the *PHOX2B* gene are correlated with increased severity of the respiratory phenotype, associated symptoms, and age of onset.[97] For example, patients with 20/27 and 20/33 genotypes, indicating the presence of 7 to 13 extra alanine nucleotides above the baseline 20 present in normal *PHOX2B* genes, often require ventilatory support during both sleep and wakefulness.[98] Patients with the genotype *PHOX2B* 20/25 have less severe disease and are more likely to present during adulthood.[99,100] It is thought that children's respiratory rate is elevated compared to adults, and as children age their respiratory rate decreases, which may unmask hypoventilation due to decreased tidal volume breaths.[101] Initial screening is done using gel electrophoresis which evaluates for polyalanine repeats and other common non-polyalanine repeat mutations associated with CCHS. A confirmatory *PHOX2B* gene sequencing test can be done if the screen is negative but the suspicion for CCHS remains high.[98]

When diagnosed in the neonatal period, symptoms include oxyhemoglobin desaturations, cyanosis, apneas most prevalent during sleep, and, possibly, cardiopulmonary arrest. Alveolar hypoventilation is most severe during NREM sleep.[102] Additionally, decreased body temperature, developmental delays, ability to breath hold for prolonged time period, constipation, esophageal dysmotility, and pupillary abnormalities are seen.[101] Phenotypically, children typically have flat forehead, box-like face shape, deep philtrum, and downturned lips.[103] Patients presenting after infancy may have evidence of right heart failure, developmental delay, or seizure disorder.[98] If presenting in adulthood, often evidence of right heart failure, polycythemia, and chronic, hypercarbic respiratory failure are seen. Respiratory decompensation typically occurs with respiratory illness, after receiving general anesthesia, during pregnancy, or with alcohol consumption.[100,104]

Awake manifestations of CCHS include decreased ventilatory response to exertion or increased metabolic demand, resulting in severe hypoxia and hypercarbia during exercise and illness. Affected persons may exhibit autonomic dysregulation, manifesting as bradycardia, sinus pauses, decreased heart rate variation in response to exercise or exertion, attenuated positional blood pressure fluctuations, and abnormalities of pupillary constriction.[101,105] There are also known associations with Hirschsprung disease and neural crest tumors, including neuroblastomas and ganglioneuroblastomas.[106,107]

Unrelated to a mutation in the *PHOX2B* gene, there are acquired forms of central hypoventilation resulting from neurologic injury, including trauma, ischemia,[108] infection, mass lesions, Chiari malformation with tonsillar herniation,[109] or demyelinating disease.

■ Special Circumstances

Important to consider clinically are special circumstances that impact CCHS, including illness, air travel, pregnancy, and use of centrally acting substances.

Illness

Due to an inability to augment ventilatory in response to increased metabolic demand, affected individuals may require nocturnal ventilation or continuous (24 h/day) ventilation during illness.[93]

Air Travel

In patients with intact chemoreceptors, as partial pressure of oxygen decreases during air travel or in high-altitude environments, respiratory rate increases. In those with CCHS, this respiratory augmentation does not occur; therefore, they should have preflight assessment to determine if supplemental oxygen is needed. Additionally, ventilators or pacing transmitters, supplemental oxygen, and oxygen monitors should be available for use on the aircraft.[93,110]

Pregnancy

Pregnancy and delivery are associated with increased metabolic demand that cannot be met in patients with CCHS. Some pregnant women require increased ventilatory support during their pregnancies; however, many are stable on their pre pregnancy treatment regimens.[111] For women with diaphragmatic pacers (DP) in place prior to pregnancy, the device has been shown to effectively treat hypoventilation during pregnancy and vaginal delivery. Some women experience discomfort with DP during the third trimester. With cesarean delivery, noninvasive positive pressure ventilation should be utilized due to pain associated with DP use following abdominal surgery.[112]

Centrally Acting Substances

Central depressants may exacerbate existing nocturnal hypoventilation; as a result, patients should be carefully monitored when these agents are administered. Commonly, patients with CCHS require close monitoring in the postprocedural period, as they will not demonstrate respiratory distress, despite inadequate oxygenation or ventilation due to blunted or absent chemosensitivity and ventilatory response.[113] Ventilatory support is often needed in the postprocedural period, even if the patient is awake.[93] Additionally, patients should be counseled against the use of alcohol, as it may lead to adverse events, such as coma or fatal nocturnal hypoventilation.[104,114]

■ Treatment Modalities for CCHS

By definition, patients afflicted with CCHS require nocturnal ventilatory support; however, they may require 24-h support during periods of illness, or even when well, depending on their genotype and respiratory phenotype. Goal values for gas exchange are an oxygen saturation of at least 95% measured by pulse oximetry, and Pa_{CO_2} of 35 to 45 mm Hg or $ETCO_2$ values between 30 and 35 mm Hg.[115] Regardless of the form of ventilatory support, continuous overnight pulse oximetry is recommended, and periodic CO_2 monitoring should be done to ensure adequacy of ventilation. Ventilatory support may be given either via IMV via tracheostomy or by NIPPV. Diaphragmatic pacing is another permanent, invasive option for ventilatory support. Less commonly used, negative pressure ventilation has documented efficacy in treating this condition.[116]

Invasive Mechanical Ventilation

The majority of infants who are diagnosed with CCHS require tracheostomy placement due to their immature respiratory system and lack of circadian rhythm, making timing of implementation of NIPPV challenging and potentially dangerous.[98,101] Additionally, young children may dislodge their NIPPV mask, which could be potentially fatal. Lastly, for children requiring prolonged ventilatory support there is a concern of midface hypoplasia due to pressure that the NPPV mask exerts on the midface. The American Thoracic Society recommends use of invasive ventilation via tracheostomy until the child is 6 to 8 years of age, as this mode of ventilation is associated with higher oxygen levels and less risk of adverse neurocognitive sequalea.[117] A retrospective review evaluating neurodevelopmental outcomes of patients with CCHS found that infants treated with tracheostomy and IMV before 3 months of age had improved cognitive outcomes compared with infants undergoing tracheostomy after 3 months of age, as well as those exclusively treated with NIPPV.[118]

Uncuffed, small-diameter tracheostomy tubes are recommended due to the decreased the risk of tracheomalacia and the opportunity to maintain phonation; however, the tradeoff is that due to the small lumen, the tubes are prone to obstruction by secretions; in addition, leak occurs as the tracheostomy tube is uncuffed and fails to form a seal with the tracheal wall. As a result, tracheostomy care must be routine, and ventilator settings need to be adjusted to overcome intrinsic air leak.

As children reach school age, a social stigma in response to tracheostomy tubes is often encountered. As a result, families and patients are likely to inquire about alternative methods of ventilation. A decannulation algorithm for children has been reported.[119] The process was started if the child was conscious, could manage his or her secretions with suction requirements <1 time per day, demonstrated no airway anomalies on bronchoscopy, and required only nocturnal IMV, and if the patient and family were motivated to transition to NIPPV. Patients were able to transition to nocturnal ventilation only if they could keep their end-tidal CO_2 <45 mm Hg and oxygen saturation >93% while awake and spontaneously breathing.[94] The protocol was used in four children with an average age of 8.9 years. Progressive increases in the duration of tracheostomy capping, while also increasing the duration of nocturnal NIPPV was the basis for the transition. Children achieved decannulation approximately 1 year after initiation of the protocol. Tracheocutaneous fistula was surgically closed 12 months after decannulation. In a separate study, adjustment to NIPPV was achieved within as little of a week for most children.[120] Other potential methods of decannulation include sequential downsizing of tracheostomy tube prior to capping.[94,121]

Noninvasive Positive Pressure Ventilation

Although IMV is the recommended ventilatory modality for young children,[117] cases in which infants have been treated solely with NIPPV for years have been reported.[120,122–124]

Bilevel positive airway pressure (BPAP) is the NIPPV modality of choice. As patients with CCHS have periods of apnea, a mandatory timed mode is needed; however, a straight timed mode can be uncomfortable; hence, the spontaneous/timed (S/T) mode is most commonly employed.[125] In order to provide a stable tidal volume (assuming lung mechanics are constant), fixed levels of EPAP and IPAP are chosen. However, since lung mechanics and airway resistance are not constant over time, a trend has developed toward greater use of adaptive algorithms for ventilation, including average volume-assured pressure support (AVAPS)/intelligent volume-assured pressure support (iVAPS).

In a head-to-head comparison of BPAP S/T with iVAPS in eight children with CCHS, the NREM peak PtcCO$_2$ median was significantly lower in the iVAPS group compared with fixed BPAP S/T. No difference in PtcCO$_2$ during REM sleep or in sleep quality or sleep architecture was noted between the two groups. However, sleep efficiency trended toward improvement in the iVAPS algorithm. Interestingly, no difference was observed in tidal volume, minute ventilation, or adherence rates. It is unclear whether this peak PtcCO$_2$ reduction equates to long-term improvements in neurocognitive function, since peak PtcCO$_2$ was below 50 mm Hg in all patients except one during a BPAP therapy S/T mode titration.[126] Another case study documented improvement in PtcCO$_2$ variability after transitioning a 10-month-old infant from BPAP S/T to VAPS.[123] Use of VAPS algorithm is limited in infants as it has a minimum tidal volume requirement of 50 mL.

Negative Extrathoracic Pressure Ventilation

Negative extrathoracic pressure ventilation (NPV) has been successfully used in patients with CCHS. NPV involves generating subatmospheric pressure around the patient's chest, which causes chest wall and upper abdominal expansion, as well as downward diaphragmatic movement, resulting in inspiration. The negative pressure generated is proportional to the tidal volume delivered. Devices that accomplish this are the chest shell (cuirass) ventilator, wrap ventilator, and Port-a-lung.[113] This mode of ventilation was made popular during the polio epidemic, but it hasn't gained widespread use due to its lack of portability, requirement of supine sleep, and risk of vocal cord opening and inspiratory effort asynchrony, resulting in obstructive apneas.[98,127]

Diaphragmatic Pacing

Diaphragmatic pacing involves insertion of electrodes into the phrenic nerve that, when activated, cause diaphragmatic contraction resulting in inspiration. Lead wires connect the phrenic nerve electrodes to receivers located under the patient's skin. External antennas placed on top of the skin over the receivers interact with a battery-powered transmitter worn by the patient, which serves as the impulse driving electrode stimulation and regulating breathing. The receiver converts the transmitter impulse to electrical current, and the voltage is proportional to diaphragmatic contraction and tidal volume.[94] The duration of the impulse equates to inspiratory time. Pediatric patients generally need bilateral phrenic nerve electrode placement for adequate ventilatory support.

These pacers can be used as the sole method of ventilation in patients requiring nocturnal support. Alternatively, in patients requiring 24-h ventilatory support, diaphragmatic pacers can be used during the day to allow for increased mobility and functional independence. Patients will still require either NPPV or negative pressure ventilation at night, as pacing for more than 12 to 16 h/day is not recommended due to risk of diaphragmatic fatigue.[93,94] Initially, the diaphragm fatigues easily and requires a slow increase in duration of stimulation to enable the patient to tolerate 12 to 16 h of stimulation daily. During this time, backup methods of ventilation should be employed.[113] Pacing may begin 4 to 6 weeks after electrode implantation and, on average, takes 6 months to reach a pacing duration of 12 to 16 h.[128]

Toddlers and children with diaphragmatic pacers should be evaluated every 6 months for adequacy of inspiratory time and tidal volume generated by the device, whereas older children and adults can be evaluated annually.[98] Additionally, patients with DP may develop upper airway obstruction and should be evaluated for possible obstructive apneas and hypopneas prior to decannulation if a tracheostomy is in place.[129] If diaphragmatic pacers are used during pregnancy, the recommendation is that the woman undergo PSG with oxygen and carbon dioxide monitoring to ensure adequacy of ventilatory support.[112] There have been no identified diaphragmatic or phrenic nerve complications of long-term DP in patients using this mode of ventilation for up to 30 years.[113]

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

Given the prevalence of COPD, an appreciation of the significance of hypercapnia in this disorder, as well as its management is of paramount importance.

Chronic Hypercapnia in COPD: Pathophysiology

COPD may cause both hypoxemic and hypercapnic chronic respiratory failure. The development of diurnal hypercapnia in patients with COPD is a combination of gas exchange and diffusion abnormalities, parenchymal distortions leading to an increased dead-space ventilation (Vds) fraction, mechanical impartment of the respiratory system, and a primary or acquired blunted ventilatory response to hypercapnia. Pa$_{CO_2}$ does not usually increase above normal until the FEV$_1$ decreases to about 20% to 25% of predicted normal values. However, the CO$_2$ chemoreceptor response may affect this curvilinear relation.

As discussed previously in this chapter, increases in lung dead space and abnormalities in ventilation/perfusion relationships impair CO$_2$ elimination and O$_2$ uptake. Increases in physiologic dead space require greater than normal levels of ventilation and tidal volume to maintain eucapnia. Maintenance of "normal tidal volume" in the setting of increased dead space predisposes to CO$_2$ retention because of an unfavorable Vds/VT. Minute ventilation is increased still further by hypoxemia.

Increases in ventilation require increases in airflow, tidal volume, and respiratory rate. This process often results in dynamic hyperinflation and increased TLC and FRC. These changes are multifactorial in origin: decreased elastic recoil secondary to emphysema, increased transpulmonary pressures due to tonic inspiratory muscle activation, increased laryngeal resistance, and the shift of tidal breathing to the upper portion of the flow–volume curve, which results in insufficient time to achieve passive exhalation to FRC, ultimately producing dynamic hyperinflation.

In presence of hyperinflation due to COPD, the diaphragm is able to generate pressures better than expected on the basis of hyperinflation alone. However, the diaphragm in these patients is also lower in the chest cavity and, despite a supraphysiologic neural drive, the diaphragm's ability to descend during inspiration is reduced, as is rib cage expansion. As hyperinflation progresses, diaphragmatic contraction may result in paradoxical deflation, rather than expansion of the rib cage, reducing the ability of the diaphragm to increase lung volumes and, ultimately, making inspiration dependent on other inspiratory muscles.[130] The effects of diaphragmatic dysfunction on ventilation are most evident during REM sleep (Fig. 142-9).

In addition to this mechanical disadvantage, the diaphragmatic muscle fibers in patients with COPD show reduced force generation per cross-sectional area, reduced myosin heavy chain content per half sarcomere, decreased Ca^{2+} sensitivity of force generation, and slower cross-bridge cycling kinetics. Inspiratory muscle weakness is a major determinant of chronic hypercapnia in COPD.[131]

Chronic hypercapnia occurs in some patients with COPD, but not in all.[132,133] Some patients admitted to the hospital with acute hypercapnia revert to normocapnia following recovery, while others remain hypercarbic in absence of nocturnal NIPPV. Data support

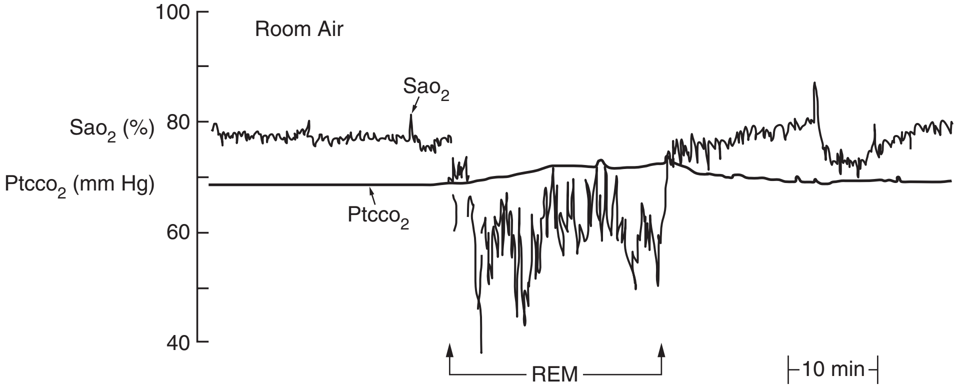

Figure 142-9 SpO_2 is reduced predominantly during REM sleep, mirroring an elevation in $PtcCO_2$ in patients with COPD. This desaturation pattern is typically seen in hypoventilatory states. *(Reproduced with permission from McNicholas WT. Chronic obstructive pulmonary disease and obstructive sleep apnoea-the overlap syndrome. J Thorac Dis. 2016;8(2):236–242.)*

the notion that persistent hypercapnia is a poor prognostic indicator for patients with COPD, and that survival in patients with hypercapnic COPD is shorter than in those with normocapnia or reversible hypercapnia.[134] Persistent hypercapnia after an exacerbation is associated with excess mortality[135] and early rehospitalization.[136]

Noninvasive Positive Pressure Ventilation in COPD

Long-term oxygen therapy (LTOT) is well recognized as the standard of care in patients with COPD with chronic hypoxemic respiratory failure and is associated with improved survival. Notably, chronic hypercapnia is a determinant of mortality in COPD.[137,138] Patients with COPD with chronic hypercapnia are more likely to be hospitalized than those without hypercapnia; the admissions are often followed by an accelerated clinical decline.[139,140] Hospital admissions for exacerbations of COPD carry a 5-year mortality near 50%.[141]

Correcting hypercapnia is a plausible intervention to improve the prognosis in this group of patients. In hypercapnic patients with COPD, NIPPV results in reduced lung hyperinflation and expiratory muscle load, in addition to increased chemosensitivity to CO_2; these findings suggest NIPPV may result in improved ventilatory performance and, ultimately, in reduced Pa_{CO_2}.[142,143]

Several trials support the observation that NIV and LTOT reduce COPD-related hospital admissions.[144,145] A pivotal study[146] supports the use of home noninvasive ventilation in patients with persistent hypercapnia for 2 to 4 weeks after resolution of an acute exacerbation of COPD that resulted in acute hypercarbia requiring acute noninvasive ventilation. This randomized trial showed improvement in time to readmission or death when home NIPPV was added to LTOT in patients with persistent hypercapnia following an admission for an acute exacerbation of COPD (Fig. 142-10).

Screening patients with COPD for persistent hypercapnia with a Pa_{CO_2} of at least 52 mm Hg after they have received NIV in the acute setting, and introducing home NIPPV, results in reduced readmissions. The number needed to treat (NNT) is six patients to avoid one readmission.[146]

Home NIPPV in patients with severe COPD improves ventilatory response to hypercapnia,[147] resulting in an improved adaptive response to acute hypercapnia during an exacerbation. Data also suggest that high-pressure noninvasive ventilation (PS or IPAP-EPAP $\geq$ 15 cm H_2O) may result in airway remodeling, decreased dynamic hyperinflation, and improved V/Q ratios.[148] The resultant reduction in Pa_{CO_2} and exacerbation frequency may also be supported by increased secretion of IL-6 and TNF in the lungs, leading to improved lung neutrophil function.[149]

Pressure support (bilevel S/T) is the preferred noninvasive ventilatory mode in COPD. As mentioned previously, high-intensity BiPAP should be used (IPAP-EPAP or pressure support > 15 cm H_2O). The use of a rather short Ti and the avoidance of high set respiratory rates decreases the possibility of dynamic hyperinflation by promoting a shorter inspiratory phase and a longer expiratory time, resulting in a low I:E ratio. Pressure control (PC) should be avoided, as patient-generated tachypnea may result in dynamic hyperinflation, as all breaths (spontaneous and timed) will be supported throughout the set Ti.

The addition of VAPS may prove beneficial in this group of patients. The ability to set a target Vt or MV assures a steady

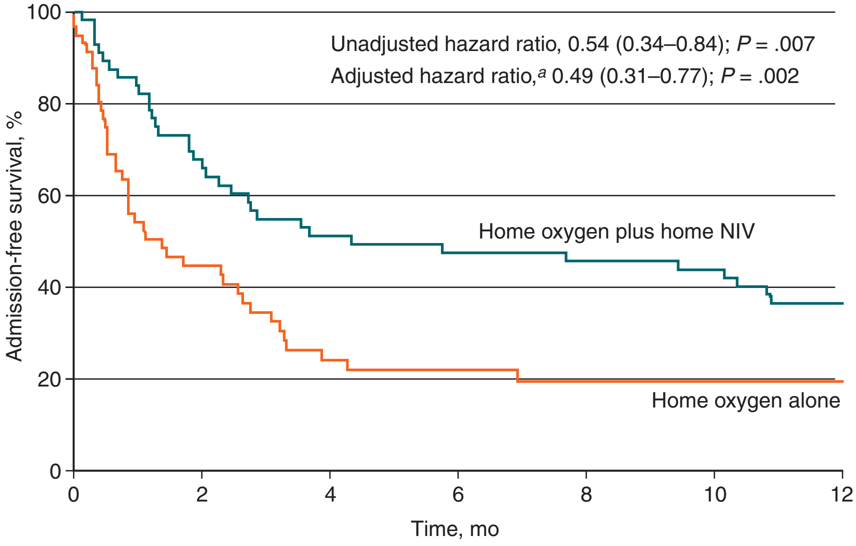

Figure 142-10 Kaplan-Meier survival plot of time to readmission or death from randomization to the end of trial showing a significant improvement in admission-free survival in the NIPPV group.[146]

ventilation, even in the setting of disease progression or clinical fluctuations, allowing theoretically for more precise control of Pa_{CO_2} toward eucapnia.

Some data suggest that BIPAP with AVAPS mode facilitates rapid recovery in pH, Pa_{CO_2}, and reduction in length of stay (LOS) compared with BIPAP S/T mode[150] AVAPS has also found to improve exercise tolerance and multiple domains of health-related quality of life when randomized versus BPAP S/T.

The addition of autotitrating EPAP to AVAPS (AVAPS AE) also provides additional benefit in overlapping COPD-OSA.

DEDICATIONS

Jennifer J. Dorsch:

This chapter is dedicated to the memory of my parents, Mike and Teri Dorsch.

Jorge I. Mora:

To my daughters, Ana and Isabel, my infinite source of inspiration.

CHAPTER 143

Oxygen Therapy and Toxicity

Matthew Wemple
Erik R. Swenson

INTRODUCTION

Oxygen was discovered in the late 18th century chiefly through the work of three scientists. Joseph Priestley, a minister in England, made his discovery after attempting to melt mercuric oxide using a magnifying glass and the sun's rays. The vapor that was produced by this melting allowed a candle to burn brighter, and Priestley later discovered the vapor could be used in place of air to keep a mouse alive. He first published his findings in 1775. In a similar way to Priestley (i.e., by burning mercuric oxide), Carl Scheele, a pharmacist in Sweden, independently made the same discovery earlier in 1772, but did not publish his results until 1777.[1] After being told about this new vapor during a 1774 visit to Paris by Joseph Priestley, the French chemist Antoine Lavoisier devised quantitative experiments that he used to prove the existence of this element and its role in combustion. He named the element "oxygen," meaning "sharp-begetter"—"oxy" meaning sharp, "gen" meaning begetter—as he believed the element was a necessary element to form acids and published his research in 1777. Scheele beat Priestley by several years but was deprived of priority because Lavoisier denied receiving a letter Scheele later claimed to have sent in September 1774 describing his 1772 discovery of what he called "fire air." Scheele's claim of priority remained unconfirmed, until his missing letter (received on October 15, 1774) was finally made public in 1992 in Paris, 218 years later. It now resides at the French Academie de Sciences. Lavoisier's guilt was kept secret in the effects of his wife and scientific assistant, Madame Lavoisier. Lavoisier failed on several occasions to credit either Priestley or Scheele for contributing to the one of the most important discoveries in the history of medicine and science.[1]

Soon after its discovery, oxygen began to be used as a medicine and cure-all for many respiratory diseases, including "dropsy," "consumption," and asthma. However, suspicions about the safety of oxygen therapy were raised almost as soon as it was discovered and even before the element was named. In 1775, Joseph Priestley wrote of oxygen: "A moralist, at least, may say that the air which nature has provided for us is as good as we deserve."[2]

Rigorous scientific evaluation of the potential toxicities of oxygen did not occur until the work of James Lorrain Smith, an Edinburgh pathologist, who first published the pulmonary pathologic alterations associated with oxygen exposure in 1899. It was also recognized around this time that under ambient air, the arterial blood was already at near-maximal oxygen-carrying capacity, putting into doubt the utility of further increasing the fraction of inspired oxygen. Following these observations, the use of therapeutic oxygen fell into some disrepute.

In the early 1920s, supplemental oxygen therapy was reevaluated. This was occurring as the detrimental effects of tissue hypoxia were being recognized, along with their reversibility with supplemental oxygen. Since the mid-20th century, especially with the advent of improved oxygen delivery systems, mechanical ventilation, and the modern intensive care unit, the use of oxygen has become a standard prescribed therapy for a multitude of cardiac and respiratory diseases. Oxygen therapy is now common in the outpatient setting. As of 2005 in the United States, approximately 1 million people receive long-term oxygen therapy (LTOT) from the Medicare Program, with total reimbursement costs related to LTOT exceeding 2 billion dollars per year.[3]

In this chapter, the physiology of hypoxia at the tissue level and mechanisms of arterial hypoxemia are discussed. In addition, various clinical assessments of hypoxemia, indications for acute and LTOT, and available methods of noninvasive oxygen administration are considered. Finally, the pathophysiology and clinical manifestations of pulmonary oxygen toxicity are addressed, along with the increasingly recognized potential for oxygen toxicity in other organ systems.

TISSUE OXYGENATION

Ultimately, the primary goal of supplemental oxygen therapy is to ensure sufficient oxygen delivery to all organs and tissues. Therefore, one must understand the causes, consequences, and mechanisms of tissue hypoxia to understand the indications for supplemental oxygen in patient care.

Tissue hypoxia is governed by the balance between oxygen delivery and oxygen utilization. Generally, failures in oxygen delivery to the mitochondria lead to most instances of tissue hypoxia. Oxygen delivery is determined by the cardiac output (Q) and the oxygen content of arterial blood, as described by the formula:

$$\mathrm{D}_{\mathrm{O}_2}\ \text{(oxygen delivery)} = \mathrm{Q}\ \text{(cardiac output)} \times \mathrm{Ca}_{\mathrm{O}_2}\ \text{(oxygen content of arterial blood)} \tag{1}$$

where $\mathrm{Ca}_{\mathrm{O}_2}$ is calculated by the formula:

$$\mathrm{Ca}_{\mathrm{O}_2}\ (\text{ml } \mathrm{O}_2/\text{dL}) = (1.34 \times \text{hemoglobin concentration} \times \mathrm{Sa}_{\mathrm{O}_2}) + (0.0031 \times \mathrm{Pa}_{\mathrm{O}_2}) \tag{2}$$

where $\mathrm{Sa}_{\mathrm{O}_2}$, is the arterial hemoglobin oxygen saturation (in the equation a fraction rather than percentage) and $\mathrm{Pa}_{\mathrm{O}_2}$ is the oxygen tension or partial pressure of arterial blood.

From this formula, the causes of poor oxygen delivery can be narrowed to three categories: low cardiac output states (i.e., various forms of shock), low hemoglobin concentration states (i.e., anemia), and low $\mathrm{Sa}_{\mathrm{O}_2}$ states (i.e., arterial hypoxemia and genetic or acquired hemoglobinopathies). Note that a low oxygen tension, although often leading to low arterial hemoglobin saturation, does not contribute appreciably to oxygen delivery. This can be seen numerically in the above formula for $\mathrm{Ca}_{\mathrm{O}_2}$, where the $\mathrm{Pa}_{\mathrm{O}_2}$ is multiplied by 0.0031 (reflecting a very low solubility) and, therefore, contributes little to the final total blood oxygen concentration. It is important to point out that supplemental oxygen therapy addresses only arterial hypoxemia. For other causes of tissue hypoxia, more specific therapies are generally required, such as vasoactive agents or intravenous fluid administration to reverse distributive and hypovolemic shock, and blood transfusions for anemia.

Along with the primary basis of poor oxygen delivery, tissue hypoxia can also occur in the setting of histotoxic hypoxia, which occurs when cells, for a variety of reasons, are unable to utilize oxygen for aerobic metabolic respiration. This is classically seen in cyanide poisoning, in which the cyanide molecule inhibits the mitochondrial enzyme cytochrome c oxidase, and the cell is subsequently unable to use oxygen in the Krebs cycle to produce adenosine triphosphate (ATP) via the mitochondrial electron transport chain. This leads to far greater amounts of glycolysis in the effort to produce sufficient ATP anaerobically, profound lactic acidosis, and cell and tissue death. Administration of oxygen is indicated if arterial P_{O_2} is low, but it will not, by itself, reverse the toxicity of cyanide or other mitochondrial poisons; other antidotes must be given (generally, sodium nitrite, amyl nitrite, and sodium thiosulfate).[4]

Another cause of decreased oxygen utilization may occur in the setting of sepsis. In this case, oxygen is not utilized by tissues due to both mitochondrial damage and abnormal shunting of blood from a variety of insults at the endothelial and microvascular levels.

Finally, oxygen may be excessively utilized by tissues relative to oxygen delivery. This may occur in hypermetabolic states, such as thyrotoxicosis[5] and fever,[6] and certain exogenous poisons such as in salicylate overdose.

ARTERIAL HYPOXEMIA

It is important to distinguish the terms *hypoxia* and *hypoxemia*. Hypoxia may be thought of as the functional equivalent of ischemia. It is not associated with acidosis from CO_2 retention and failure to clear other metabolites and refers to a lack of or misuse of oxygen at the tissue level. Hypoxemia refers to the blood's oxygen content and can be more formally defined as a validated lower oxygen tension in the blood. In other words, when a patient's Pa_{O_2} and, therefore, Sa_{O_2} are low, the patient is hypoxemic. Since arterial hypoxemia is a major cause of tissue hypoxia, the cause of which is most likely to be reversed or improved with oxygen therapy, its major etiologies are discussed below.

The driving force of oxygen diffusion across the alveolar–capillary barrier into the blood depends on the partial pressure of oxygen in the alveolus (PA_{O_2}). Thus, arterial hypoxemia results from either reduction of the inspired oxygen tension or dysfunction of the respiratory system leading to regions of the lung with lower PA_{O_2}. Along with the reduction of inspired oxygen tension (such as at altitude), there are four other pathophysiologic causes of arterial hypoxemia (Table 143-1).

Alveolar hypoventilation leads to a diminished PA_{O_2} and resultant decrease in Pa_{O_2} and Sa_{O_2}. It may constitute the final common pathophysiologic denominator for a variety of pulmonary and nonpulmonary disorders leading to hypercapnia and hypoxemia. Examples of nonpulmonary disorders leading to these derangements include narcotic overdose, which reduces the central drive to breathe; abdominal compartment syndrome, which can mechanically reduce ventilation due to abdominal distension; and control of ventilation disorders such as obstructive sleep apnea and the obesity–hypoventilation syndrome.

Another pathophysiologic cause of hypoxemia arises with defects in diffusion of oxygen across the alveolar–capillary membrane, as, for example, in fibrotic lung diseases and interstitial pneumonias. The increased barrier to oxygen diffusion is detected as a reduced diffusing capacity of carbon monoxide (DL_{CO}), although many other conditions lead to reductions in diffusing capacity. Diffusion limitation generally coexists with ventilation–perfusion mismatch. Its effects on oxygenation often become clinically prominent in states of increased cardiac output and greater tissue oxygen extraction (such as exercise) in the setting of high altitude and fibrotic or interstitial lung disease.[6] These higher-output states lead to reduced red cell capillary transit times and thus less time for complete diffusional equilibration of oxygen between alveolar gas and capillary blood with resultant hypoxemia.

Clinically, besides hypoventilation, most frequently observed pathophysiologic mechanisms of hypoxemia are ventilation–perfusion mismatch and shunt. Ventilation–perfusion mismatch generally results when focal (or sometimes diffuse) areas of diminished ventilation arise relative to persistent pulmonary blood flow. Clinical examples include obstructive lung diseases such as COPD and asthma, and interstitial edema leading to reduced ventilation, but continued perfusion. The hypoxemia resulting from a relative lack of ventilation to these areas can generally be overcome simply by increasing the fraction of inspired oxygen (FI_{O_2}); that is, with the use of supplemental oxygen. In the setting of ventilation–perfusion mismatch, without oxygen supplementation, reflex hypoxic pulmonary vasoconstriction (HPV) occurs helping to reduce the mismatch. HPV, when extensive throughout the lung, may ultimately lead to increased pulmonary artery pressure and, if severe and prolonged, cor pulmonale.

Shunt occurs when a fraction of pulmonary blood flow effectively bypasses ventilated alveolar regions or flows through unventilated regions. Examples of the latter include alveolar filling processes, such as cardiogenic alveolar edema, pneumonia, drowning, and atelectatic lung in which ventilation is absent, but perfusion maintained (at least in part, as it is often blunted by HPV). Examples of the former include right-to-left lung shunting processes such as atrial septal defect and large vessel intrapulmonary arteriovenous malformations. Compared with ventilation–perfusion mismatch, increasing the alveolar concentration of oxygen in the setting of shunt has less of an effect on improving arterial oxygenation. In other words, as shunt fraction is increased, the resulting hypoxemia will become increasingly refractory to increases in FI_{O_2}.

Finally, when tissue hypoxia is severe, or when increased tissue oxygen utilization is present, the oxygen content of venous blood returning to the right heart may be profoundly reduced—detected as a low oxygen saturation of venous blood (Sv_{O_2}). A low Sv_{O_2}, in combination with hypoventilation, ventilation–perfusion mismatch, or shunt, will also lead to worsening arterial hypoxemia. This pathophysiologic constellation may be observed when patients with severe lung disease and poor oxygen delivery are physically active, anemic, or have high metabolic demands due to critical illness. Hemoglobin desaturation can then be seen.

CLINICAL ASSESSMENT OF TISSUE HYPOXIA

To use oxygen therapy correctly, clinicians must recognize the presence of tissue hypoxia and its etiology. With this knowledge,

TABLE 143-1 Causes of Arterial Hypoxemia and Response to Oxygen Therapy

Cause	Clinical Examples	Response (Dependent on Magnitude of F_{IO_2})
Decreased inspired oxygen	Altitude (reduced P_{IO_2})	Appreciable rapid increase in Pa_{O_2}
Alveolar hypoventilation	COPD, obesity hypoventilation	Increase in Pa_{O_2}, may depress ventilation, however, and cause or worsen hypercapnia
Diffusion defect	Interstitial pneumonitis	Moderately rapid increase in Pa_{O_2}
Ventilation–perfusion mismatch	COPD, asthma	Moderately rapid increase in Pa_{O_2}
Shunt	Atrial septal defect, with right-to-left shunting, pulmonary AVMs	Variable increase in Pa_{O_2}, depending on size of shunt

TABLE 143-2 Signs and Symptoms of Acute Hypoxia

System	Signs and Symptoms
Respiratory	Tachypnea, dyspnea, cyanosis, pulmonary hypertension
Cardiovascular	Increased cardiac output, palpitations, tachycardia, bradycardia, arrhythmias, hypotension, angina, vasodilation, diaphoresis, shock
Central nervous	Headache, impaired judgment, inappropriate behavior, confusion, euphoria, delirium, restlessness, papilledema, seizures, obtundation, coma
Neuromuscular	Weakness, tremor, asterixis, hyperreflexia, incoordination
Metabolic/renal	Sodium and water retention, lactic acidosis, acute tubular necrosis

the clinician can determine who may benefit from supplemental oxygen. Furthermore, the degree of hypoxia must be assessed to determine the optimal dosage of oxygen. In this way, one can balance oxygen's benefits and potential toxicities. Unfortunately, tissue hypoxia is not directly measured by any one test. Instead, a combination of clinical and laboratory parameters is used to determine its severity. In the case of tissue hypoxia caused by isolated arterial hypoxemia, measurement of arterial oxygen saturation can be an excellent guide to appropriate oxygen therapy.

Clinical Manifestations

Clinical manifestations of tissue hypoxia are variable and nonspecific. Whether hypoxia develops acutely or is chronic influences a patient's presentation. Patients with chronic hypoxia often have minimal symptoms. Symptoms and signs of acute hypoxia are outlined in Table 143-2. The most prominent findings are dyspnea, tachypnea, tachycardia, and respiratory distress. A frequently observed finding is an acute change in mental status, ranging from agitation to delirium to coma. Cardiac arrhythmias are common. Cyanosis is generally a late finding and is often unreliable in diagnosing hypoxia, as it may be absent in the setting of anemia and with poor peripheral perfusion.

Laboratory Assessment

Distinction between tissue hypoxia and arterial hypoxemia is important in applying various laboratory studies in the clinical evaluation. To determine if tissue hypoxia, that is, hypoxia in end-organs, is present, measures such as serum lactate (elevated in ischemia) and Sv_{O_2} (reduced in ischemia or low cardiac output states) are generally used. Evaluation for anemia by measuring hemoglobin or hematocrit is also important in this context.

When the cause of tissue hypoxia is isolated arterial hypoxemia, measurements of Pa_{O_2} and Sa_{O_2} provide appropriate surrogates of oxygen delivery and, therefore, tissue hypoxia. Values are derived from arterial blood–gas measurements. Since Sa_{O_2} and Pa_{O_2} have a generally predictable relationship according to the oxygen–hemoglobin dissociation curve, measuring Sa_{O_2} may alone be sufficient to assess arterial hypoxemia. This is done noninvasively using pulse oximetry; the estimated Sa_{O_2} is designated as Sp_{O_2}. Importantly, various toxins, such as carbon monoxide (CO) and those that result in methemoglobinemia will disrupt the predictable relationship between Sa_{O_2} and Pa_{O_2} as measured by pulse oximetry (see next section). Under these circumstances, pulse oximetry cannot be relied upon to evaluate arterial hypoxemia. This can only be done by co-oximetry that utilizes four wavelengths of light rather than two as with pulse oximetry.

Pulse Oximetry

Pulse oximetry is an important diagnostic tool that is now widely utilized in hospitals, in outpatient settings, and at home. The general principles of this technology are useful to understand, as are its limitations.

First proposed conceptually in the 1930s and developed further in the mid-20th century, the underlying principle of oximetry is Beer's law, which states that concentration of an unknown substance dissolved in a solvent can be determined by its light absorption:[8]

$$L_{out} = (L_{in} \times e) - (D \times C \times a) \tag{3}$$

where

L_{out} is the intensity of transmitted light through the substance
L_{in} is the incident light
D is the distance the light travels
C is the concentration of the substance (in this case, oxyhemoglobin or reduced hemoglobin)
a is the absorption coefficient

When light is passed through a finger, ear lobe, or other tissue, most of it is absorbed by connective tissue, skin, bone, and venous blood, and the amount absorbed is constant. However, with each heartbeat, pulsatile flow of arterial blood occurs, allowing the pulse oximeter to detect changes in light absorbance at two wavelengths, 660 nm (red) and 940 nm (infrared). Since reduced hemoglobin and oxyhemoglobin have different absorptions at these two wavelengths, the concentration of oxyhemoglobin relative to total hemoglobin can be deduced.

Several limitations to pulse oximetry exist, which can be inferred from its basic principles.[9] Any substance in the blood with similar absorption at the two wavelengths employed will interfere with accuracy. This is clinically important in the evaluation of two acquired hemoglobinopathies—carboxyhemoglobinemia and methemoglobinemia, and any genetic hemoglobin variants.

Carboxyhemoglobin has a very similar absorption coefficient at 660 nm as oxyhemoglobin; at 940 nm, it has minimal light absorption. Therefore, no matter what the relative concentrations of hemoglobin molecules saturated with CO versus O_2, Sp_{O_2} will be constant (generally about 90%–95%).

In methemoglobinemia, a condition in which the iron moiety of hemoglobin is reduced to the ferric state, methemoglobin is characterized by equalization of absorption coefficients at 660 nm and 940 nm. Equal absorption at these two wavelengths translates into an Sa_{O_2} ranging from 83% to 87%, which is what the pulse oximeter inevitably reads as methemoglobin concentration increases. Furthermore, methylene blue, an antidote for methemoglobinemia and used also in other clinical conditions, also affects absorption of light at 660 nm and may falsely lower Sp_{O_2}.

Given that pulse oximetry relies upon pulsatile flow, the technology cannot be used in conditions of low flow, such as cardiac arrest, profound shock, or in patients treated with nonpulsatile cardiac support such as with extracorporeal membrane oxygenators or ventricular assist devices. Errors also occur when venous pulsatility is prominent, such as in severe tricuspid regurgitation. In this case, the pulsatility of venous blood, with its higher concentration of deoxyhemoglobin, may result in artificially low readings of oxygen saturation. When profound arterial hypoxemia exists, for example, Sa_{O_2} <70%, the accuracy of pulse oximetry declines, as the technology was never validated for humans at lower saturations.

Other Assessments of Hypoxemia

Several other calculated assessments of hypoxemia are useful in assessing the degree of respiratory dysfunction.

$\mathrm{Pa}_{\mathrm{O}_2}/\mathrm{FI}_{\mathrm{O}_2}$

$\mathrm{Pa}_{\mathrm{O}_2}/\mathrm{FI}_{\mathrm{O}_2}$ (P/F ratio) requires an arterial blood gas specimen. For example, consider a patient breathing gas with an $\mathrm{FI}_{\mathrm{O}_2}$ of 0.80, who has a $\mathrm{Pa}_{\mathrm{O}_2}$ 240 mmHg. The P/F ratio is 240/0.8 or 300. The ratio, considered to reflect the magnitude of derangement in O_2 transfer across the lung and thought to be relatively unaffected by differences in $\mathrm{FI}_{\mathrm{O}_2}$ among measurements, is most useful in mechanical ventilation, when accurate determination of $\mathrm{FI}_{\mathrm{O}_2}$ is possible. In the setting of acute hypoxemia, a P/F ratio of <300 indicates clinically important abnormal gas exchange, and a P/F ratio <200 indicates severe hypoxemia.

Alveolar–Arterial (A–a) Difference

The A–a difference (also called somewhat imprecisely the A–a gradient) measures the difference in alveolar oxygen tension and arterial oxygen tension. This measurement, which requires an arterial blood gas, is determined as:

$$\text{A-a difference} = \mathrm{PA}_{\mathrm{O}_2} - \mathrm{Pa}_{\mathrm{O}_2} \tag{4}$$

$\mathrm{PA}_{\mathrm{O}_2}$ is calculated using the alveolar air equation:

$$\mathrm{PA}_{\mathrm{O}_2} = (\mathrm{FI}_{\mathrm{O}_2} \times [\mathrm{P}_{\mathrm{atm}} - \mathrm{PH_2O}]) - (\mathrm{Pa}_{\mathrm{CO}_2}/\mathrm{R}) \tag{5}$$

where

$\mathrm{FI}_{\mathrm{O}_2}$ is the fraction of inspired oxygen
$\mathrm{P}_{\mathrm{atm}}$ is the atmospheric pressure (760 mmHg at sea level)
$\mathrm{PH_2O}$ is the partial pressure of water (47 mmHg at 37 degrees C)
$\mathrm{Pa}_{\mathrm{CO}_2}$ is the arterial carbon dioxide partial pressure
R is the respiratory quotient (which, in a normal resting steady state, is usually 0.8, depending on the patient's nutritional intake, but may approach 1.0 with critical illness and high sympathetic tone)

A "normal" A–a difference on room air is often considered to be 10 mmHg. However, two important factors affect the "normal" value. The first is patient's age, the influence of which can be expressed numerically according to the formula:

$$\begin{aligned}&\text{Normal A–a difference breathing ambient air}\\ &\quad = 2.5 + 0.21 \times \text{age in years}\end{aligned} \tag{6}$$

The second is $\mathrm{FI}_{\mathrm{O}_2}$: The higher the $\mathrm{FI}_{\mathrm{O}_2}$ and resultant $\mathrm{PA}_{\mathrm{O}_2}$, the larger is the A-a PO_2 difference and vice versa. This is because for any extent of venous admixture the shallower the slope of the hemoglobin dissociation curve over which gas exchange occurs (from mixed venous PO_2 to alveolar PO_2), the larger is the A-aPO2 difference. In contrast if the mean alveolar PO_2 is low due to hypoventilation or being at high altitude, the A–a difference falls below normal and may underestimate or obscure the diagnosis of lung dysfunction.[10] Note the distinction in this regard also with respect to the P/F ratio described previously.

INDICATIONS FOR OXYGEN THERAPY

Supplemental oxygen is a drug with indications, contraindications, and a therapeutic window. Oxygen dosage should be titrated as precisely as possible and oxygen administration monitored closely with respect to clinical benefits and potential toxicities. Indications for oxygen therapy may be considered in both acute and chronic settings. In addition, special circumstances under which oxygen is used therapeutically warrant special discussion, including hyperbaric administration (oxygen delivered at 2–3 atmospheres of pressure) and oxygen therapy during air travel.

■ Acute Indications for Oxygen Therapy

Indications for acute, short-term supplemental oxygen therapy, listed in Table 143-3, are based upon guidelines established by the American Association of Respiratory Care and other organizations.[11–13]

Usually, when a patient presents with respiratory distress, supplemental oxygen is administered until an assessment of hypoxemia is made. The clearest indication for oxygen therapy is arterial hypoxemia, and supplemental oxygen is generally administered when the $\mathrm{Pa}_{\mathrm{O}_2}$ is <60 mmHg, which normally corresponds to an $\mathrm{Sa}_{\mathrm{O}_2}$ or $\mathrm{Sp}_{\mathrm{O}_2}$ of 89% to 90%. When the $\mathrm{Pa}_{\mathrm{O}_2}$ drops below 60 mmHg, oxygen saturation may drop precipitously, leading to a much lower arterial oxygen content and resultant possible tissue hypoxia.

TABLE 143-3 Guidelines for Acute Oxygen Therapy

Accepted Indications
• Documented hypoxemia, defined as $\mathrm{Pa}_{\mathrm{O}_2}$ below the normal range. Usually $\mathrm{Pa}_{\mathrm{O}_2}$ <60 mmHg or $\mathrm{Sa}_{\mathrm{O}_2}$ <90%.
• Acute care situation in which hypoxemia is suspected, such as respiratory distress. Requires substantiation of hypoxemia (by $\mathrm{Sa}_{\mathrm{O}_2}$ or $\mathrm{Pa}_{\mathrm{O}_2}$) in a reasonable time.
• Severe trauma
• Severe acute anemia
• Acute myocardial infarction with hypoxemia
• Low cardiac output with metabolic acidosis
• Hypotension (systolic blood pressure <100 mmHg)
Questionable Indications
• Acute myocardial infarction without hypoxemia
• Dyspnea without hypoxemia (palliative)
• Sickle cell pain crisis
• Pneumothorax

Data from Kallstrom TJ, American Association for Respiratory Care (AARC). AARC Clinical Practice Guideline: oxygen therapy for adults in the acute care facility—2002 revision & update. Respir Care. 2002;47(6):717–720; O'Driscoll BR, Howard LS, Davison AG; British Thoracic Society. BTS guideline for emergency oxygen use in adult patients. Thorax. 2008;63 Suppl 6:vi1–vi68; Fulmer JD, Snider GL. American College of Chest Physicians (ACCP)–National Heart, Lung, and Blood Institute (NHLBI) Conference on oxygen therapy. Arch Intern Med. 1984;144(8):1645–1655.

As noted previously, the common pathophysiologic causes of hypoxemia, ventilation–perfusion mismatch, and hypoventilation respond readily to supplemental oxygen. Hypoxemia secondary to right-to-left shunt is less responsive to supplemental oxygen; when the shunt fraction exceeds 20% to 25%, hypoxemia persists, despite administration of inspired gas with $\mathrm{FI}_{\mathrm{O}_2}$ of 1.0. In the case of hypoxemia due to alveolar hypoventilation, oxygen therapy often improves $\mathrm{Sa}_{\mathrm{O}_2}$ and oxygen delivery, but it does not correct the hypercapnia and underlying cause of respiratory dysfunction; restoration of ventilation must be pursued.

An oxygen saturation target of 92% to 96% is reasonable for patients at sea level who are hypoxemic and who have normal baseline lung function.[12] In certain circumstances, such as profound anemia, the target may be higher in an attempt to maximize the oxygen content of arterial blood before blood transfusion can be accomplished. Conversely, in patients who have abnormal control of respiration, such as those with chronic hypercapnia, a lower $\mathrm{Pa}_{\mathrm{O}_2}$ goal may be more appropriate (as discussed later in this chapter).

Use of supplemental oxygen may be indicated in a few clinical scenarios other than arterial hypoxemia. As discussed earlier, patients with severe anemia may benefit from enhanced arterial oxygen content and delivery, as may patients in cardiac and respiratory arrest. Similarly, trauma victims and critically ill surgical patients may benefit from early oxygen therapy to improve tissue hypoxia and for its hypertensive effects in hypovolemic shock. In patients with carbon monoxide poisoning, in whom pulse oximetry readings are unreliable, supplemental oxygen increases $\mathrm{Pa}_{\mathrm{O}_2}$ and blood oxygen content by both increasing the dissolved oxygen content and immediately displacing some of the CO bound to hemoglobin to increase the percentage of oxyhemoglobin. More importantly, it shortens the half-life of carboxyhemoglobin and hastens the clearance of CO. With administration of pure oxygen, the half-life of carboxyhemoglobin is 70 to 80 min,[14] compared with a half-life of 320 min when a patient breathes ambient air.[14] Under hyperbaric conditions, when pure oxygen is delivered at higher atmospheric pressure, the half-life is shortened even further to under 10 minutes. Hyperbaric oxygen is generally employed when carboxyhemoglobin levels are high (>25%) and there is evidence of end-organ damage, such as cardiac ischemia or alterations in sensorium,[16] although use of hyperbaric oxygen in this setting is currently controversial.

Several other disorders may benefit from administration of supplemental oxygen, although supportive data in these settings are lacking or equivocal. Oxygen therapy is often used in cluster headaches,[17] sickle cell pain crises (although this is falling out of favor),[18] palliative relief of dyspnea without hypoxemia,[19] and pneumothorax in patients who do not have a chest tube (in an effort to facilitate resorption of pleural air).[20,21] Administration of supplemental oxygen has also been proposed to reduce postoperative nausea and vomiting and to alleviate nausea associated with medical transport in ambulances.[22] Use of supplemental oxygen in uncomplicated myocardial infarction and stroke is common but controversial; the topic is discussed in more detail below. Finally, hyperbaric oxygen is sometimes used in an effort to accelerate healing of complicated, chronic wounds arising in the setting of peripheral or microvascular disease.[23] Hyperbaric oxygen therapy is widely accepted as the therapy of choice in decompression sickness (Chapter 93).[24]

Indications for Long-Term Oxygen Therapy

The use of LTOT has been growing as our ability to deliver oxygen in outpatient settings has improved. Criteria for administering LTOT have become well established, generally in the context of chronic obstructive pulmonary disease (COPD). Table 143-4 outlines the guidelines of the American Thoracic Society (ATS) for LTOT in Chronic Lung Disease.[25] The guidelines are largely based on the data derived from two major trials.

TABLE 143-4 Physiologic Indications for Long-Term Oxygen Therapy (LTOT) in COPD[a]

Pa_{O_2}	Sa_{O_2}	LTOT Indication	Qualifier
<55 mmHg	≤88%	Absolute	None needed
55–59 mm Hg	89%	Relative with qualifier	Presence of any of the following signs of cor pulmonale: • History of dependent edema • Polycythemia (Hematocrit >55%) • P pulmonale on ECG (P wave >3 mm in leads II, III, or aVF)
≥60 mmHg	≥90%	None unless qualifier	• Severe exercise desaturation (ambulatory use only)

[a] *Generally used in other conditions as well.*

Data from Jacobs SS, Krishnan JA, Lederer DJ. Home oxygen therapy for adults with chronic lung disease. An official American Thoracic Society clinical practice guideline. Am J Respir Crit Care Med. 2020;202(10):1345–1359; Continuous or nocturnal oxygen therapy in hypoxemic chronic obstructive lung disease: a clinical trial. Nocturnal Oxygen Therapy Trial Group. Ann Intern Med. 1980;93(3):391–398; Long term domiciliary oxygen therapy in chronic hypoxic cor pulmonale complicating chronic bronchitis and emphysema. Report of the Medical Research Council Working Party. Lancet. 1981;1(8222):681–686.

The first trial, published in 1980, is the Nocturnal Oxygen Therapy Trial (NOTT).[26] In NOTT, 203 hypoxemic patients with COPD were randomized to the treatment with either nocturnal (at least 12 h) or continuous oxygen. Patients who received nocturnal oxygen therapy alone had a higher mortality at both 12 and 24 months (40.8% at 24 months) compared with those who received continuous oxygen therapy (22.4% at 24 months).

The second trial, published in 1981, is the British Medical Research Council Domiciliary (BMRCD) trial.[27] In this trial, 87 patients with hypoxemia and COPD were randomized to receive either no oxygen therapy or at least 15 h/day of supplemental oxygen. Similar to the NOTT trial, mortality was significantly higher in the no-oxygen group. Both trials studied patients in a stable medical state on maximal therapy and nonsmoking, who had Pa_{O_2} <55 mmHg or <60 mmHg if they had polycythemia or cor pulmonale. Currently, Sp_{O_2} <88% can also serve in lieu of an arterial blood gas measurement.

From these two trials, in patients with COPD and hypoxemia, we can infer that supplemental oxygen for >15 h/day is better than no oxygen at all, and that continuous supplemental oxygen is better than nocturnal-only therapy. The entry criteria for these trials form the basis of the current Medicare criteria and ATS guidelines for LTOT. Based on the BMRCD trial, most prescriptions for oxygen are written for at least 15 h/day. The data from the two trials have been extrapolated to other cardiopulmonary diseases complicated by chronic hypoxemia for which data from large trials are lacking, including cystic fibrosis, restrictive lung diseases, and chronic cardiac diseases.

In patients with COPD whose hypoxemia does not meet resting criteria or who have exercise induced hypoxemia, a recent multicenter trial did not support long term oxygen therapy. The 2016 Long Term Oxygen Therapy Trial (LOTT) randomized 738 patients with a resting desaturation of 89% to 93% or exercise-induced desaturation (defined by desaturation during the 6-min walk test) to either LTOT versus no LTOT. In the intervention arm, LTOT was delivered as either continuous oxygen therapy, for those patients with moderate resting desaturation, or oxygen therapy only during sleep and exercise, for those with exercise-induced desaturation. Patients randomized to the intervention arm did not experience life extension, lower rates of first hospitalization, or improvement in quality of life compared with controls.[28]

Finally, nocturnal supplemental oxygen is sometimes prescribed in patients with significant desaturation while sleeping. There is currently no clear evidence to support this practice in COPD.[29,30] Patients with nocturnal desaturation in the absence of underlying lung disease will often have obstructive sleep apnea or obesity hypoventilation syndrome, for which noninvasive positive pressure ventilation, rather than supplemental oxygen, constitutes primary and more effective therapy.[31]

Indications for Oxygen Therapy in Air Travel

An important consideration for clinicians who manage patients with lung disease is determining the need for supplemental oxygen during air travel.

Most commercial aircraft fly at cruising altitudes between 25,000 and 45,000 ft, which would normally result in a very low inspired oxygen tension (PI_{O_2}). Airplane cabins, however, are generally pressurized to an equivalent altitude of 8,000 ft, which results in an oxygen tension of approximately 108 mmHg (the PI_{O_2} at sea level is 149 mmHg). In patients with lung disease, this reduced PI_{O_2} may result in marked reductions in PA_{O_2} and Pa_{O_2}, placing the patient at risk for hypoxemia.

Prior to travel, the patient should have a thorough medical evaluation, with consideration for reevaluating pulmonary function tests, specifically spirometry and DL_{CO}, and obtaining an arterial blood gas. For patients whose Pa_{O_2} ≥70 mmHg (Sp_{O_2} >95%) at ground level, their in-flight Pa_{O_2} will likely exceed 50 mmHg, which is generally considered adequate for rest and minimal physical activity. For patients with a more marginal Sp_{O_2} or Pa_{O_2} and other risk factors, a 6-min walk test or other evaluation may be considered.[32]

The 6-min walk test may be a reliable and practical way of estimating the cardiopulmonary reserve that patients require to deal with the physiologic demands of a reduced PI_{O_2} during flight. Although the entire medical evaluation must be taken into account, if a patient has an abnormally low 6-min walk distance, has significant dyspnea during the test, or experiences a decline in Sp_{O_2} to <85%, the patient will likely need supplemental oxygen during air travel.

Finally, in anticipation of air travel, a hypoxia altitude simulation test (HAST) may be performed (Chapter 31).[33] In this test, an arterial blood gas is drawn just prior to administration of a gas mixture with an FI_{O_2} of 15.1%. Another arterial blood gas is drawn 20 min later, while the patient breathes the hypoxic gas mixture. If the Pa_{O_2} is <50 mmHg, administration of supplemental oxygen during flight is recommended. If the Pa_{O_2} is between 50 and 55 mmHg, further testing should be considered, including a 6-min walk test. Reviews are available that address oxygen therapy and air travel including testing options and recommended liter flow rates to achieve adequate oxygenation.[34]

TECHNIQUES OF OXYGEN ADMINISTRATION

When choosing an oxygen delivery device for a given patient, the clinician must consider the degree of hypoxemia, the specificity required with regard to setting the FI_{O_2} (which depends on the patient's ventilatory control), and the patient's minute ventilation. The oxygen flow that the device can deliver, the adjustability and precision of that delivery, and the comfort and cost of the device are additional considerations.

Oxygen delivery devices utilized in the acute setting may be divided into low-flow and high-flow delivery systems. The required flow depends on the patient's degree of hypoxemia and minute ventilation. Patients with a high minute ventilation or who are profoundly hypoxemic require high-flow devices, if they do not require mechanical ventilation. Patients with more moderate degrees of hypoxemia may only need low-flow systems, which are generally more comfortable.

■ Low-flow and Variable Performance Oxygen Devices

Low-flow systems deliver only a fraction of the patient's minute ventilation as pure oxygen. The maximum flow in these systems is 15 L/min. Since a patient's tidal volume and inspiratory flow rate usually vary from breath to breath, and the delivered flow of oxygen from the device is constant, the fraction of inspired oxygen for any given breath is impossible to predict. For example, when a patient takes very deep breaths, more ambient air is entrained, but the flow of pure oxygen is constant, thereby diluting the administered FI_{O_2}. Conversely, when a patient has a reduced minute ventilation or is taking very shallow breaths, the amount of entrained ambient air is minimal, and the FI_{O_2} inspired may be far greater than what might be expected. Table 143-5 illustrates this important principle mathematically. The variation in FI_{O_2} with minute ventilation must be considered when administering oxygen to patients with chronic CO_2 retention who are at risk for worsening hypercapnia with excessive oxygen therapy. Because of the uncertainty of the FI_{O_2} delivered by low-flow devices, they are sometimes referred to as "variable performance devices."

Nasal Cannulae

Nasal cannulae allow comfortable delivery of oxygen and unimpeded communication and access to oral intake. The cannula rests just below the nares (Fig. 143-1) and delivers a constant flow of pure oxygen, generally ranging from 2 to 6 L/min. At 6 L/min or higher, the patient may experience discomfort, excessive mucosal dryness, and epistaxis. The continuous flow creates an anatomic reservoir of oxygen in the nasopharynx from which the patient draws during inspiration. Contrary to popular belief, even if a patient is a "mouth-breather," the gas inhaled is oxygen enriched because of the effect of the nasopharyngeal reservoir. In certain disease states, such as chronic obstructive pulmonary disease (COPD), with a prolonged expiratory phase, end-expiratory flow may be present, which limits the creation of the anatomic reservoir and "mouth-breathing" effects may be present.[35] Although FI_{O_2} varies widely with nasal cannulae (as described above), an approximation of FI_{O_2} based on oxygen flow rate can be derived (Table 143-6). Typically, FI_{O_2} increases by 0.03 to 0.04 with each 1-L increment in flow.

Several variations in nasal cannulae design may reduce oxygen waste. The moustache-style reservoir (Fig. 143-1C) contains a soft, inflatable reservoir with a volume of approximately 20 ml. During exhalation, the reservoir fills with oxygen. During inspiration, the patient initially draws from the reservoir and then, when the reservoir is depleted, from the continuous flow of the cannula. This acts to deliver a bolus of oxygen early in the course of the inspiration, while reducing wasted oxygen during expiration. Generally, patients can be maintained at a slightly lower flow rate using the moustache-style cannula compared with a regular nasal cannula.

Another modification is the pendant reservoir cannula (Fig. 143-1B). This device consists of a reservoir worn on the chest like a pendant. The reservoir is attached to a nasal cannula with tubing of

TABLE 143-5 Effects of Minute Ventilation on FI_{O_2} in Low-flow Systems

	Respiratory Distress	Relief of Respiratory Distress
Minute ventilation	30 L/min (40 breaths/min × 750 ml/breath)	5 L/min (10 breaths/min × 500 ml/breath)
O_2 flow rate	2 L/min	2 L/min
Calculation of inspired O_2 concentration (FI_{O_2})	2 L/min of 100% oxygen + 28 L/min of 21% oxygen (room air drawn into mask) = 30 L/min minute ventilation Thus, $FI_{O_2} = \frac{(1.0 \times 2) + (0.21 \times 28)}{30} = 0.26$ (**26%** FI_{O_2})	2 L/min of 100% oxygen + 3 L/min of 21% oxygen (room air drawn into mask) = 5 L/min minute volume Thus, $FI_{O_2} = \frac{(1.0 \times 2) + (0.21 \times 3)}{5} = 0.53$ (**53%** FI_{O_2})

slightly greater diameter than normal. The pendant reservoir cannula provides a similar function to the moustache-style cannula.

Simple Oxygen Masks

Oxygen masks can deliver higher oxygen flow rates than nasal cannulae; they entrain less ambient air and, therefore, can generate a higher FI_{O_2}. In addition, the configuration of simple masks (Fig. 143-2A) enables an enlarged reservoir of oxygen for inhalation. With nasal cannulae, the reservoir comprises anatomic dead space in the airway, such as the nasopharynx. With a well-fitting oxygen mask, the reservoir is expanded to include the volume within the mask. Generally, flow rates for simple masks range from 5 to 12 L/min, which usually requires some ambient air to be entrained via the side ports of the mask to meet the patient's minute ventilatory needs. Given the higher flow rates delivered using face masks, a humidifier is also often required. The flow rate of a simple mask should never be <5 L/min; below this level, carbon dioxide rebreathing may occur, along with an increased resistance to inspiration.

12 (50)	0.40
15 (41)	0.50

[a] *Number in parentheses indicates total flow of entrained ambient air with Venturi mixture.*

As is the case with nasal cannulae, predicting the actual F_{IO_2} delivered by simple oxygen masks is difficult, since the F_{IO_2} varies with the size of the patient's tidal volumes, inspiratory flow rate, and minute ventilation. Simple masks are also more uncomfortable, making eating and communicating challenging. Because they cover the mouth, aspiration is a risk with any mask.

Reservoir Masks

A reservoir mask is similar to a simple mask but has an attached reservoir of 600 to 800 ml, resting below the patient's chin. Generally, the mask provides flow between 8 and 15 L/min, which keeps the reservoir bag at least half full. Reservoir masks include partial rebreather and nonrebreather types (Fig. 143-3).

When using a partial rebreather mask, the patient exhales approximately the first one-third of the expired tidal volume into the reservoir. That volume is derived predominantly from anatomic dead space and, consequently, its O_2 content is high and CO_2 content low. The reservoir bag is filled with the exhaled volume and continued oxygen inflow, while the remainder of the patient's tidal volume is exhaled via the mask's side ports and edges. A patient with a high minute ventilation can sometimes deflate the reservoir. As with simple oxygen masks and nasal cannulae, the F_{IO_2} the patient is receiving cannot be determined precisely at any point in time.

The nonrebreathing reservoir mask (Fig. 143-2B) is similar to the partial rebreather, with the exception of a one-way valve at the exit of the reservoir bag. The valve ensures that no exhaled air enters the reservoir (i.e., air can travel only in an inward direction), enabling delivery of 100% oxygen. The mask also incorporates one-way valves on its side ports to minimize the inhalation of ambient air. When using a nonrebreathing reservoir mask, oxygen flow should be set high enough to prevent deflation of the reservoir bag—usually about 15 L/min. Currently available masks do not fit securely enough to ensure a delivered F_{IO_2} of 1.0. Typically, these masks provide a maximum F_{IO_2} of 0.8 to 0.9; the F_{IO_2} may be even lower (0.60–0.8) in the setting of very high minute ventilation.[36]

■ High-flow or Fixed-Performance Oxygen Devices

High-flow oxygen devices deliver a constant F_{IO_2} and are, therefore, sometimes referred to as "fixed performance devices." The devices allow for a fixed F_{IO_2} by providing very high flows of pure oxygen that exceed the patient's minute ventilation, sometimes by a factor of four. Along with very high flow rates, the devices incorporate oxygen reservoirs whose volumes exceed the patient's anatomic dead space. Since the F_{IO_2} is predictable, high-flow devices are ideal for patients who have precise oxygen needs that should be neither exceeded nor unmet. Patients for whom high-flow devices are prescribed may be severely hypoxemic and must be monitored closely for the possible need for noninvasive or invasive mechanical ventilation.

Air-entrainment Masks (Venturi Masks)

The Venturi mask consists of a mask, a jet nozzle, and entrainment ports (Fig. 143-2D). Oxygen is delivered under pressure via the jet nozzle, which acts to dramatically increase the velocity of the gas. The high-velocity gas entrains ambient air via the entrainment ports. Depending upon the size of entrainment ports, size of the jet nozzle, and flow rate of oxygen, a predictable F_{IO_2} can be delivered.

Typically, the Venturi mask has interchangeable or adjustable valves that enable the clinician or respiratory therapist to better titrate the F_{IO_2} to the patient's needs. Humidification is sometimes difficult to ensure and requires the use of an aerosol-entrainment collar over the jet orifice and entrainment port. Humidification increases the density of the entrained air, slows the speed of entrainment, and thereby reduces the amount of room air entrained, resulting in a higher F_{IO_2}. Although described as a high-flow device, air-entrainment masks generally can only ensure a high-flow rate when the F_{IO_2} is <0.3.[36] As the F_{IO_2} increases above 0.3, the devices are unable to deliver flow rates of 40 L/min (as less ambient air is entrained) and are considered variable performance devices. However, the ability of these masks to deliver an exact F_{IO_2} at lower levels of F_{IO_2} makes them ideal for patients with chronic lung disease who require a specific F_{IO_2} due to the risk of hypercapnia from hyperoxia. In fact, for treatment of patients with COPD in emergency departments, the British Thoracic Society recommends oxygen administration using a Venturi mask to ensure an appropriate F_{IO_2}.[12]

High-flow Generators

High-flow generators are used to ensure noninvasive delivery of a constant, high concentration of inspired oxygen. High-flow generators are capable of delivering gas in excess of 40 to 60 L/min. From the generator, gas is routed through a heated humidifier, similar to that used for mechanical ventilators. A large reservoir is often placed in line between the humidifier and aerosol face mask. The face mask may incorporate valves that ensure that no rebreathing occurs. Given the high flows delivered, a constant F_{IO_2} is achieved, regardless of the patient's minute ventilation and fit of the mask. When precise oxygen titration is required, air–oxygen blenders are used. The blenders are metering devices that use compressed oxygen and air from a high-pressure wall source (50 psi) to generate a gas mixture that can be delivered at high flow (e.g., 100 L/min) and precise

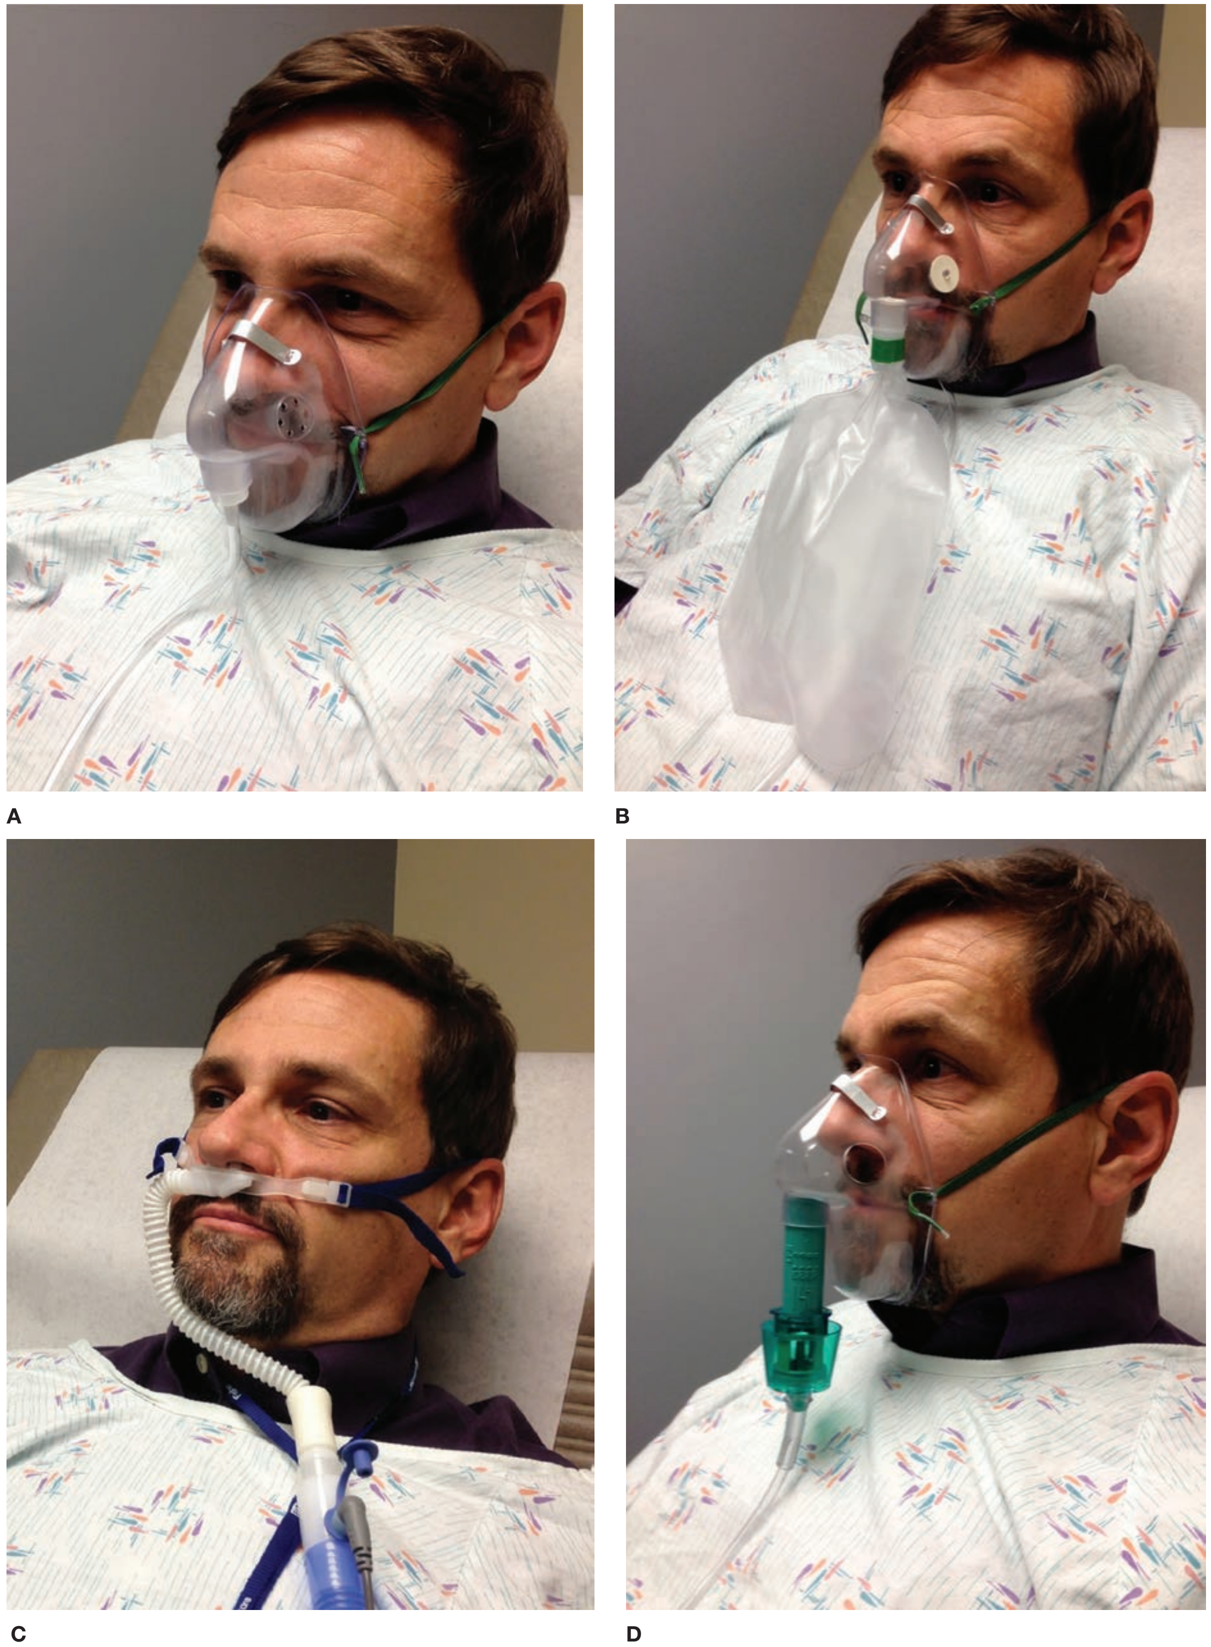

Figure 143-2 Mask oxygen delivery devices. **A.** Simple face mask. **B.** Nonrebreather mask. **C.** High-flow nasal cannulae. **D.** Venturi mask.

$\mathrm{FI}_{\mathrm{O}_2}$. The devices are noisy and require specialized personnel to set up and monitor, limiting their usage to intensive care settings.[37]

High-flow Nasal Cannulae (HFNC)

Over the past 10 years, nasal cannulae that can deliver much higher rates of flow than simple nasal cannulae have been developed (e.g., Optiflow or Vapotherm). These can be used with the same type of high-flow generators discussed above, allowing delivery of up to 60 L/min of heated, humidified oxygen. The high-flow nasal cannula interface (often abbreviated HFNC) can be more comfortable than a facemask. Physiologic benefits of HFNC compared with face mask delivery include elimination of interface dead space, washout of

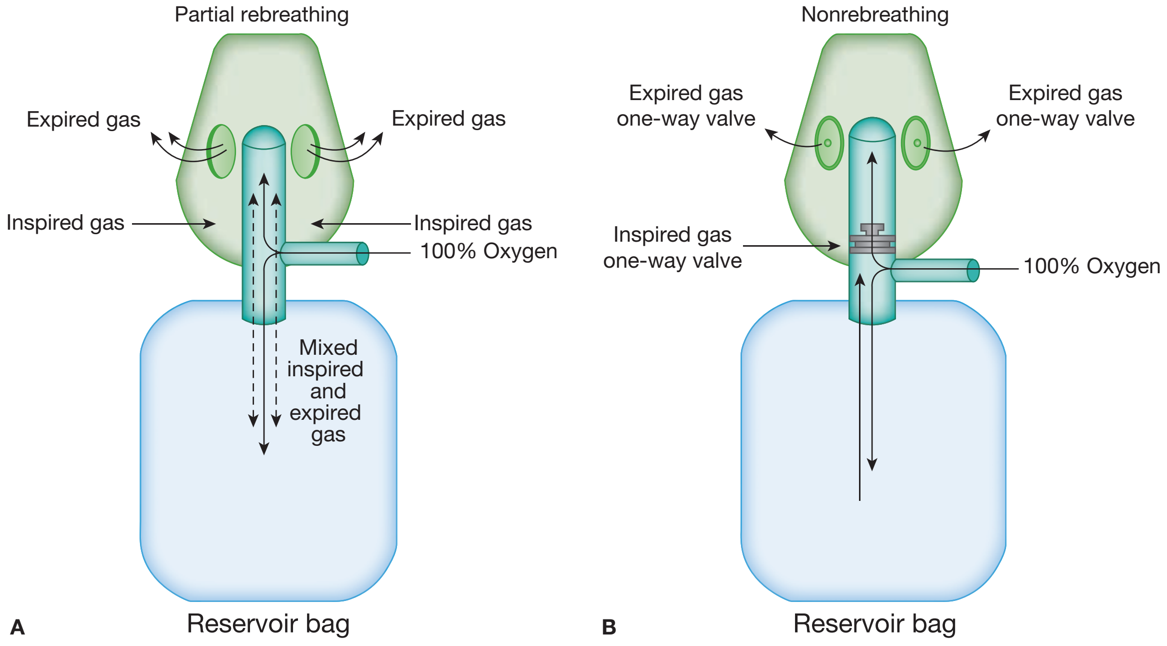

Figure 143-3 Mask reservoir bag systems, illustrating airflows with partial rebreathing (**A**) and nonrebreathing (**B**) masks. *Arrows* indicate direction of airflow.

carbon dioxide from the nasopharynx, improved thoracoabdominal synchrony and improved work of breathing, and increased positive end-expiratory pressures, up to 4 cmH_2O.[38] Use of HFNC has been studied in a number of clinical settings, including hypoxemic respiratory failure, hypercarbic respiratory failure, postoperative respiratory failure, preoxygenation for intubation, and prevention of reintubation following extubation.[39] In hypoxemic respiratory failure, randomized controlled trials have shown a lower rate of intubation compared with conventional supplemental oxygen[40,41] and noninvasive positive pressure ventilation.[40] Studies looking at prevention of reintubation have shown comparable rates of reintubation in high-risk patients compared with noninvasive positive-pressure ventilation and lower rates of reintubation compared with conventional oxygen therapy.[42]

■ Long-Term Oxygen Therapy

As noted previously, LTOT has a significant beneficial effect on survival in patients with COPD and chronic hypoxemia. However, initiation of chronic home oxygen therapy can be a substantial burden for patients. Like any therapy, LTOT requires patient adherence. Various studies have noted adherence to LTOT in only 45% to 70% of patients.[43] The barriers to adherence are many and include patient concerns of addiction and dependency, embarrassment from the "stigma" that an oxygen delivery device represents a smoking-related disease, and the associated limitations on physical activity arising from bulky ambulatory oxygen sources.[43] Therefore, appropriate counseling about the benefits (life extension, improved exercise capacity and quality of life) and demands of oxygen therapy is necessary before beginning treatment. Furthermore when considering LTOT, the clinician should consider oxygen source portability, available social and home support (e.g., friends, family, visiting nurses), and patient attitudes and beliefs, especially regarding smoking cessation. Finally, the prescribing clinician needs to facilitate sufficiently close patient monitoring to ensure long-term benefit from therapy. In the United States, oxygen therapy requires a Certificate of Medical Necessity (CMN). Continued need for LTOT must be recertified annually.

Oxygen Concentrators

Oxygen concentrators use specialized filters to eliminate other gases from ambient air, thus "concentrating" oxygen for delivery to the patient. Concentrators accomplish this by (1) using a compressor to draw ambient air into the system, (2) cooling the air (which has been heated up from the compression) using a heat exchanger, and (3) passing the air into molecular sieve beds where oxygen is concentrated. Sieve beds contain granular zeolite crystal composed of an array of small particles that separate gases according to size. Air cycles through two separate sieve beds; the cycling gradually removes nitrogen as waste and isolates oxygen, which is diverted to a product tank. The oxygen in the product tank is pressurized at 10 psi and, prior to patient delivery, is passed through a bacteria filter and flow meter. Concentrators usually can produce oxygen concentrations of 95% to 97% at 2 L/min flow; the concentration falls to 86% to 93% at 3 to 5 L/min flow (note that pure oxygen tanks provide 100% oxygen at any flow rate up to 6 L/min).[37] Oxygen concentrators include large devices (weighing about 35 lb) intended for stationary use in the home and smaller portable devices, designed for use outside the home. The larger concentrators can produce high flows (up to 10 L/min) but are often tethered by power cords. High flow rates also demand humidification, which can also be provided by most large concentrators. Portable oxygen concentrators permit patient mobility; their use is increasingly being approved for air travel.[44] They usually weigh between 5 and 10 lb. Battery life is variable, typically on the order of 2.5 h.

Liquid Oxygen

Although compressed gas oxygen is still utilized, often as an emergency supply in the home, liquid oxygen (LOx) has become standard in domiciliary systems. LOx has advantages of being more compact, requiring fewer refills, and operating at lower pressures than gaseous oxygen.

A home system of LOx typically consists of a large stationary reservoir that can hold up to 100 lb of LOx, and a smaller portable system for ambulation. The portable system can be refilled by the patient and may weigh as little as 5 lb. LOx is stored in tanks called dewars, which generally resemble a thermos bottle. The dewar consists of inner and outer containers and interposed insulating material and vacuum to maintain low temperatures.[37] Generally, LOx is more expensive than compressed gas and requires pressure-relief venting. However, LOx delivery systems consume less electricity and enable longer periods of high-flow oxygen administration.

Oxygen-conserving Devices

LTOT is expensive, and oxygen-conserving devices have been designed to limit oxygen waste. Simple oxygen-conserving devices were discussed earlier. In addition to these simple devices, electronic oxygen-conserving devices are available.

Electronic oxygen-conserving devices are triggered by the onset of inspiration and deliver oxygen in boluses, the volume of which depends on device settings. For *pulse-type devices*, a fixed volume of oxygen is delivered (based on the flow setting) each time a breath is initiated. Some pulse-type devices deliver the volume with alternating breaths, rather than with every breath. For *demand-type devices*, the volume of oxygen is delivered throughout the whole inspiratory cycle; consequently, the volume varies according to the length of the cycle. For demand-type devices, as respiratory rate decreases, the amount of oxygen conserved also decreases. In fact, demand-type devices commonly deliver an equal or greater volume of oxygen than a continuous-flow device. In the event of an electronic-conserving device malfunction, the delivery system defaults to continuous flow, often without the patient being aware.

Transtracheal Catheters

Transtracheal catheters, also considered oxygen-conserving devices, are considerably more invasive than other forms of LTOT. Transtracheal catheters require insertion directly into the trachea. Usually, this is accomplished percutaneously, using a modified Seldinger technique (similar to that used for placement of a percutaneous tracheostomy), or surgically, using a Lipkin procedure or minitracheotomy.[45]

The benefit of a transtracheal catheter is that it delivers oxygen that bypasses much of the anatomic dead space and utilizes the natural oxygen reservoir of the upper airway. Oxygen usage may be reduced by 50% to 75% with the use of a transtracheal catheter. In addition, nasal or facial irritation is minimal. Unfortunately, the catheter can be a nidus for infection and formation of "mucus balls," which rarely are fatal.[46]

OXYGEN TOXICITY

Concerns about oxygen toxicity have existed essentially since its discovery. Soon after his discovery in 1775, Joseph Priestley wrote that oxygen "might not be so proper for us in the usual healthy state of the body …" The modern study of oxygen toxicity largely focused on pulmonary oxygen toxicity and began with J. Lorrain Smith in 1899. Smith described pathologic changes of oxygen toxicity in small animals exposed to the gas at a fractional concentration of 0.4 at 4.5 atmospheres (hyperbaric oxygen).[47] He noted that with high levels of oxygen exposure in mice, "the effect was uniformly fatal, and the immediate cause of death was inflammation of the lungs … and the lungs were found postmortem to be extremely congested … the alveoli were to a great extent filled with an exudate, which was granular and fibrillated in appearance…."

Further studies were conducted in animals to confirm Smith's findings. In the late 1930s, Becker-Freysang et al. studied oxygen exposure in humans and found that with 65 h of exposure to O_2 at 730 mmHg, paresthesias, nausea, and significant decreases in vital capacity occurred.[46] In the early 1960s, a healthy volunteer exposed to 110 h of continuous high oxygen exposure experienced profound alterations in vital capacity, minute ventilation, pH, and Pa_{O_2}.[48] However, in general, the study of oxygen toxicity in humans has proved challenging. Based on animal models, information has been generated on the underlying cellular mechanisms.

■ Biochemical Basis of Oxygen Toxicity

In considering the biochemical basis of oxygen toxicity to the lungs and body, the roles of free radicals in the production of tissue damage and the protective cellular antioxidant defenses should be noted.

Free Radicals

Descriptions of the mechanisms of oxygen toxicity invariably begin with the concept of highly reactive oxygen-derived free radicals, specifically, superoxide (O_2^-), hydrogen peroxide (H_2O_2), and the hydroxyl radical (OH^-). By definition, free radicals have an unpaired orbital electron that causes oxidation of a surrounding molecule. Free radicals are ubiquitously produced during cellular oxidative metabolism; however, cells normally have the capability of neutralizing them quickly. Invariably, in hyperoxic conditions, generation of free radicals overcomes the cell's natural defenses.[49] Once formed in excess, free radicals are responsible for a cascade of effects, including lipid damage, leading to membrane dysfunction; disruption of enzymatic protein function; and nucleic acid damage.[50] Ultimately, these effects may result in cell death. In the case of nucleic acid damage, mutagenesis may occur.

Cellular Antioxidant Defenses

Various enzymes and cofactors in cells neutralize free radicals produced normally as a byproduct of mitochondrial metabolism. These neutralizing enzymes are ubiquitous in eukaryotes.[51] The prototype is the metalloprotein superoxide dismutase, which converts superoxide to hydrogen peroxide. Hydrogen peroxide so-generated is converted intracellularly to H_2O and O_2 through the actions of catalase (found in peroxisomes) and glutathione peroxidase (found in the cytoplasm). Glutathione peroxidase also repairs damaged lipids. Glutathione reductase and glucose-6-phosphate dehydrogenase regenerate glutathione, enabling its recycling as an antioxidant.

Nonenzymatic antioxidants, which are present within cells, include the vitamins α-tocopherol (vitamin E) and ascorbate (vitamin C). Other antioxidants, such as ceruloplasmin and cysteine, also are normally present in cells and the extracellular fluid. In fact, human lung tissue contains a high concentration of extracellular antioxidants and superoxide dismutase isoforms, which allow exposure to higher-concentration oxygen without development of toxicity.[52–54]

Tissue Damage in the Lungs

The cascade of reactions leading to hyperoxia-induced pulmonary tissue damage can be described in two phases.[55] Three to four days following hyperoxic exposure and generation of free radicals, an *exudative* phase commences, characterized by death of alveolar type 1 and endothelial cells. Interstitial edema is seen along with exudative alveolar filling. Neutrophil recruitment into the capillaries and interstitium is present. Alveolar epithelial damage then occurs, as neutrophils enter the alveoli, as seen in bronchoalveolar lavage specimens. A second, *proliferative* phase follows, characterized by proliferation of endothelial cells and type 2 pneumocytes. The pneumocytes cover the previously exposed basement membrane. Fibroblast proliferation also occurs in this phase. Recovery from oxygen injury is characterized by interstitial scarring and fairly normal-appearing capillary endothelium and alveolar epithelium.

■ Clinical Manifestations of Pulmonary Oxygen Toxicity

The exposure level at which oxygen toxicity occurs has not been clearly identified, although a higher FI_{O_2} experienced for a longer period of time is associated with an increased risk. Clinical oxygen toxicity is manifest in several ways. Normal subjects experience a decrease in vital capacity and fall in DL_{CO}.[56] Lung compliance is diminished.[57] Tracheobronchitis, which produces substernal chest pain and cough, also may occur.[57] Clinical toxicity is generally absent when the FI_{O_2} is <0.5. Most clinically relevant concerns over oxygen toxicity center around (1) absorption atelectasis; (2) hypercapnic respiratory failure in at-risk individuals; (3) acute respiratory distress syndrome (ARDS); and (4) hyaline membrane disease, leading to bronchopulmonary dysplasia (BPD) in newborns.[58–60]

Absorption Atelectasis

When a human breathes ambient air, oxygen in the lung passes freely from the alveoli into the capillaries and is bound to hemoglobin or dissolved in plasma. Nitrogen, however, being an inert gas, does not diffuse into the blood at any appreciable rate and thus acts to stent open the alveoli and maintain patency. For a patient breathing pure oxygen, the absence of nitrogen promotes alveolar collapse.

In a study based on mathematical modeling of alveolar collapse, the time from airway occlusion and cessation of ventilation into that region to alveolar collapse was 37 min using 3 min of ventilation with ambient air, compared with 8.7 min using preoxygenation with 100% oxygen (taking into account HPV).[61] In a clinical context, patients who received 40% oxygen just prior to extubation were shown to have less atelectasis on CT imaging compared with those who received 100% oxygen.[62] Absorption atelectasis can be observed with induction of anesthesia. Preoxygenation and resulting nitrogen washout particularly in lungs with areas of low ventilation to perfusion ratios, along with a decrease in FRC from chest wall and diaphragmatic paralysis that occurs with the use of anesthetics and neuromuscular blockade, lead to small airway and alveolar collapse.[63]

Hypercapnia in the Setting of Chronic CO_2 Retention and Hyperoxia

Patients with chronic CO_2 retention, usually in the setting of COPD, are at risk of worsening hypercapnia when exposed to high levels of inspired oxygen. Classically, this worsening of hypercapnia during excessive supplemental oxygen administration has been attributed to the suppression of hypoxic drive to breathe in the setting of a blunted hypercapnic drive. This formulation was first proposed in a case report published in the middle of the 20th century.[64] However, three other mechanisms have been proposed,[12] as discussed below.

Ventilation–perfusion mismatch is an important cause of hypoxemia in patients with COPD. As discussed previously, HPV blunts the adverse effects of a low $P_{A_{O_2}}$ due to reduced ventilation on both Pa_{O_2} and Pa_{CO_2}. When $P_{A_{O_2}}$ is increased through administration of supplemental oxygen, HPV is abolished, increasing perfusion to alveolar units that remain underventilated. In fact, they become units with even lower V_A/Q and, now, oxygen enriched. Alveolar oxygen diffuses across the alveolar–capillary membrane with a higher driving partial pressure, but because ventilation is still reduced, the gradient for CO_2 is not enhanced. The increase in perfusion comes at the expense of better ventilated units, which now do not eliminate as much CO_2 as before and as a result, $P_{A_{CO_2}}$ and thus Pa_{CO_2} increases.

An additional consideration is the *Haldane effect*—the increased capacity of deoxygenated blood over oxygenated blood for CO_2 binding. As hemoglobin molecules become deoxygenated (i.e., reduced), they more readily accept protons (H^+). Removal of dissolved protons from plasma drives formation of bicarbonate, which, in turn, is catalyzed by carbonic anhydrase:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+ \tag{8}$$

Bicarbonate is the primary form in which CO_2 is transported and eliminated from the body. Furthermore, deoxygenated hemoglobin binds CO_2 directly, forming carbaminohemoglobin. As $P_{A_{O_2}}$ and, consequently, Pa_{O_2} increase with oxygen therapy, the concentration of oxyhemoglobin increases while that of deoxyhemoglobin decreases. As a result, CO_2 and H^+ buffering capacity are depleted, diminishing venous blood's transport capacity for tissue-generated CO_2. Loss of this capacity to transport CO_2 results in a rise in Pa_{CO_2}.

Finally, since pure oxygen is of higher density than air, the increased density of oxygen-enriched mixtures may contribute to increased work of breathing in an already compromised patient.[65]

Regardless of the underlying mechanism(s), clinicians must be vigilant when administering supplemental oxygen to those with chronic CO_2 retention, especially when they are very hypoxemic and exhausted. Unfortunately, the worsening of hypercapnia with oxygen administration is unpredictable; some patients with COPD do not develop hypercapnia with hyperoxia, while others may develop frank ventilatory failure. Use of a high-performance oxygen delivery device (e.g., Venturi mask) and titration of $F_{I_{O_2}}$ to achieve a goal Sp_{O_2} of 88% to 90% in selected populations is the preferred management strategy. Isolated case reports over the years have reported poor outcomes with unregulated $F_{I_{O_2}}$, but this was incontrovertibly shown in a randomized out-of-hospital study in patients with acute exacerbation of COPD transported to hospital randomized to either high-flow O_2 or supplemental O_2 titrated to achieve Sp_{O_2} in the range of 88% to 92% with a mortality difference of 7% versus 2%.[66]

Acute Respiratory Distress Syndrome (ARDS) and Bronchopulmonary Dysplasia (BPD)

Oxygen toxicity has been implicated in the pathophysiology of ARDS, although this subject is controversial. In almost all nonhuman mammals, prolonged exposure to 100% oxygen leads to diffuse alveolar damage and, eventually, death. In humans, replicating these findings has been challenging. Conducting studies on oxygen toxicity presents ethical considerations of testing healthy human subjects. In addition, when oxygen toxicity is studied in the setting of pulmonary disease, differentiation between damage caused by the underlying lung disease and that caused by excessive oxygen exposure may be impossible. Furthermore, the situation is complicated by the fact that many inflammatory diseases evoke upregulation of antioxidant defenses. Thus, many human studies have failed to show an association between excessive oxygen exposure and development of acute lung injury or ARDS.

In a study of brain-dead patients whose normal lungs were exposed for 24 h to 100% oxygen delivered via a mechanical ventilator, only mild increases in alveolar capillary permeability were demonstrated; several more days of oxygen exposure failed to produce pathologic evidence of lung injury.[67] Similarly, another trial in postoperative cardiac patients failed to show any clinical differences between those ventilated with 100% oxygen and those ventilated with the minimal amount of oxygen needed (mean $F_{I_{O_2}}$ of 0.32).[68] Notably, an acute lung injury pattern due to oxygen toxicity may be seen in humans with prior drug exposure, as discussed below.

Premature newborns often require high levels of oxygen therapy in the setting of hyaline membrane disease—a disorder caused by surfactant deficiency and characterized by alveolar collapse and inflammation.[69] In survivors, chronic lung disease in the form of BPD is often seen. Oxygen toxicity is considered a major factor in the pathogenesis of BPD. BPD has been described in infants administered a high concentration of oxygen but not mechanically ventilated.[58] Newborns are particularly prone to damage by hyperoxia, as their cellular antioxidant defenses are not fully developed. The initial pathologic lesions of BPD resemble diffuse alveolar damage. As BPD evolves, pathologic findings include alternating areas of collapse and emphysema, hyaline eosinophilic material lining distended terminal airways, marked epithelial hyperplasia or metaplasia, peribronchial fibrosis, and elastic fibers around air sacs and lobules. Clinically, the condition presents as a persistent requirement for supplemental oxygen or mechanical ventilation following hyaline membrane disease, along with poor lung compliance and pulmonary hypertension. Most infants gradually improve after 2 to 4 months. In more severe cases, infants require prolonged mechanical ventilation and may develop cor pulmonale from severe pulmonary hypertension.

■ Potentiation of Pulmonary Oxygen Toxicity

Several drugs have well-known pulmonary toxicity and may potentiate the toxicity of oxygen. Bleomycin, an antibiotic agent first isolated from the fungus *Streptomyces verticillus* in the late 1960s,[70] has been used as a chemotherapeutic agent in the treatment of lymphomas, germ cell tumors, Kaposi sarcoma, cervical cancer, and squamous cell carcinomas of the head and neck. One mechanism by which bleomycin exerts its antitumor effect is through induction of cytotoxicity via generation of free radicals. Bleomycin forms a complex with Fe^{2+}, which is oxidized to Fe^{3+}, resulting in reduction of oxygen to free radicals. Bleomycin is also thought to exert direct effects on DNA. Along with its elimination by the kidneys, bleomycin can be deactivated by the enzyme bleomycin hydrolase, which is found in most tissues (especially the liver). However, two notable organs lack the enzyme: lung and skin.

In the lungs, bleomycin toxicity is manifested in three ways: organizing pneumonia, eosinophilic hypersensitivity, and interstitial pneumonitis, which all may progress to fibrosis. An experiment in the hamster demonstrated that high doses of oxygen may work synergistically with bleomycin to cause worsening lung injury.[71] In humans, several case reports describe ARDS in patients previously treated with bleomycin who had exposure to a high FI_{O_2} perioperatively.[72,73] However, one prospective trial failed to show an association between high levels of oxygen exposure, past bleomycin exposure, and significant postoperative pulmonary dysfunction.[74]

Another well-known potentiator of pulmonary oxygen toxicity is paraquat. Paraquat is a commercial herbicide commonly used in the United States. It is associated with considerable toxicity and mortality when ingested orally, often in suicide attempts.[75] Like bleomycin, paraquat-induced pulmonary toxicity is the result of oxidative stress arising from the generation of free radicals, leading to pneumonitis and pulmonary fibrosis. Similar to models of bleomycin toxicity, animal studies suggest worsening toxicity in the setting of higher levels of inspired oxygen.[76,77] Therefore, in managing patients with paraquat poisoning, FI_{O_2} should be minimized as much as clinically possible. Use of paraquat is banned in the European Union and in several other countries, but the herbicide is still available for agricultural use in the United States. Fulminant poisonings carry a mortality that well exceeds 50%.[78]

Other drugs studied with regard to potentiation of oxygen toxicity include disulfiram and nitrofurantoin. Disulfiram is converted in vivo to diethyldithiocarbamate, which inhibits cytosolic superoxide dismutase.[79] Metabolism of nitrofurantoin results in the production of superoxide in a similar way to paraquat. The final pathway in both cases is an accumulation of oxygen-free radicals.[80]

Finally, elements of dietary intake are also associated with potentiation of oxygen toxicity, at least in animal models.[81] Protein deficiency leads to hyperoxic damage, possibly through a lack of sulfur-containing amino acids, which are crucial to glutathione synthesis. Deficiencies in the antioxidants vitamin A and vitamin E have also been implicated in the potentiation of oxygen toxicity.[82,83]

Oxygen Toxicity in Other Organ Systems

Hyperoxia has the potential for producing toxicity in other organ systems. For example, an association between increased mortality and hyperoxia in the setting of return of spontaneous circulation (ROSC) following cardiac arrest has been reported.[84] In this large, multicenter, retrospective cohort study, patients who had a Pa_{O_2} >300 mmHg following ROSC had an odds ratio for in-hospital death of 1.8 (95% confidence interval [CI], 1.8–2.2), based on a model controlling for potential confounders. The increased mortality seen in this study was attributed to hyperoxic reperfusion injury leading to oxidative stress—specifically worsening postarrest functioning of the central nervous system. Based on the results of this study, the American Heart Association has adjusted its postarrest guidelines to emphasize titration of FI_{O_2} to maintain an oxygen saturation no greater than 94%. Prospective data are not currently available to prove causation. A recent study also described increased mortality in patients with hyperoxemia immediately following emergency department intubation, which correlated strikingly with the degree in elevation of Pa_{O_2}.[85]

In a retrospective study conducted at a single trauma center, higher mortality was noted in patients with traumatic brain injuries exposed to hyperoxia (Pa_{O_2} >200 mmHg) compared to normoxia.[86] Patients with hyperoxic exposure were more likely to have low Glasgow coma scores (3–8) on discharge than those who were normoxic. In the same study, patients with hypoxemia also had worse outcomes compared to those who were normoxic, emphasizing the importance of close and continued monitoring using pulse oximetry. Another study of patients treated with hyperbaric oxygen showed worse neurological outcomes.[87]

In the case of acute myocardial infarction (AMI), controversy exists regarding oxygen therapy. When treating patients with myocardial ischemia who are hypoxemic, oxygen is absolutely indicated, as it can be life-saving. However, when a patient with AMI is not hypoxemic, whether supplemental oxygen is beneficial is unclear. A double-blind randomized trial conducted in the late 1970s compared oxygen therapy (6 L/min) with no oxygen therapy in 157 patients with uncomplicated AMI.[88] In patients who received oxygen, higher rates of sinus tachycardia and a greater rise in myocardial enzymes were noted, along with no difference in mortality (actually, a trend toward improved mortality was seen in the no-oxygen arm). Several reasons for the potential deleterious effects of hyperoxia in an AMI have been proposed. In healthy humans, hyperoxia has been shown to induce coronary vasoconstriction. Furthermore, in critically ill patients, high-flow oxygen therapy may lead to maldistribution of microcirculatory blood flow, increased functional O_2 shunting, a reduction in total body oxygen consumption[89] and more reactive oxygen species damage in areas undergoing successful reperfusion. Although data supporting the use of supplemental oxygen in uncomplicated AMI remains absent, the practice remains nearly universal.

Finally, clinical trials and meta-analyses have examined the appropriate Sp_{O_2} target for acute care and critically ill inpatients. A single-center, open-label randomized trial was conducted over 2 years in 434 ICU patients, comparing conservative oxygen therapy (goal Sp_{O_2} 94%–98%) versus conventional oxygen therapy (accepting Sp_{O_2} to 97% to 100%). Patients randomized to conservative oxygen therapy had improved ICU mortality and a lower rate of shock, liver failure and bacteremia.[90] A subsequent meta-analysis examined results from 25 clinical trials which enrolled a total of 16,037 inpatients, with varying diagnoses including stroke, trauma, sepsis, myocardial infarction and emergency surgery. Results showed an increased hospital mortality in patients receiving a liberal oxygen strategy (relative risk, 1.21; 95% CI, 1.03–1.43).[91] However, two trials published in 2020 failed to show an effect of a conservative oxygenation strategy on ventilator-free days in mechanically ventilated patients with lung disease[92] or 28-day survival in patients with ARDS.[93] Current British Thoracic Society Guidelines advocate for a target Sp_{O_2} range of 94% to 98% in most adult inpatients, and 88% to 92% in patients at risk of hypercapnic respiratory failure.[94]

CONCLUSION

Since its discovery, oxygen has been successfully utilized in medicine, revolutionizing the field in the early half of the 20th century. Supplemental oxygen remains among the most common therapies provided in the inpatient setting. Oxygen therapy may improve oxygen delivery and reverse tissue ischemia. The role of supplemental oxygen in management of outpatients with chronic, severe, pulmonary, and cardiac diseases is broad. In the outpatient setting, supplemental oxygen may considerably improve quality of life in those patients willing to adapt to its use. Despite the widespread availability of supplemental oxygen and its relative ease of use, oxygen must be considered a drug with a therapeutic window, above which the potential for significant toxicity exists.

CHAPTER 144

Pulmonary Pharmacotherapy

Karen J. Tietze

Scott Manaker

A wide spectrum of therapeutic agents is currently employed in the treatment of respiratory disorders, including obstructive lung diseases. This chapter reviews the rationale for, and clinical use of, these agents in current clinical practice.

DRUG DELIVERY

Inhaled drug administration is preferred for many medical conditions. Advantages of inhaled drug administration include rapid onset of action and the ability to deliver small drug doses directly to the lungs, minimizing systemic drug exposure. Compressed air nebulizers have been in use for more than 150 years; the first metered-dose inhaler (MDI) became available in the 1950s, followed by the first dry powder inhaler (DPI) in the 1960s.[1] Many new and innovative devices have been marketed as the result of the phase-out of chlorofluorocarbon-containing MDIs.[2]

Device selection depends on drug–device availability, patient characteristics (e.g., age, cognitive function, manual dexterity), and patient preference (Tables 144-1 and 144-2).[3,4] MDIs and nebulizers share universal designs; other drug delivery devices are unique, individually patented devices.

MDIs are small portable devices that protect the medication from contamination; they are difficult to use correctly. Common drug administration errors include improper timing of actuation and inspiration and failure to inspire slowly and deeply. MDI accessory devices (e.g., spacers, valved holding chambers) decrease oropharyngeal drug deposition and reduce the need for precise "press and breathe" timing, but they are bulky, add to the cost of therapy, and must be regularly cleaned to reduce bacterial contamination and electrostatic charges within the chamber. The Respimat device is a unique, multidose liquid inhaler that uses spring-loaded energy to generate a fine aerosol mist.

DPIs are available as single-dose devices, multidose premetered devices, and multidose reservoir devices. DPIs are breath actuated, requiring rapid and forcible inhalation to aerosolize and deliver the dose; most require inspiratory flow rates of 30 to 60 L/min. Young children, the elderly, and patients with reduced lung function (e.g., during an acute exacerbation) may be unable to generate adequate inspiratory flow rates.

Nebulizers aerosolize a solution or suspension by one of the three mechanisms: compressed air or oxygen (jet nebulizers), high-frequency ultrasonic energy (ultrasonic nebulizers), and vibrating mesh. Suspensions can only be aerosolized with jet nebulizers. Nebulizers are more expensive, require more dose preparation, and take more time to deliver a dose than other drug delivery devices. However, they require less patient cooperation and may be used by patients of all ages and abilities.

TABLE 144-1 Inhaled Drug–Device Availability

Drug Class	pMDI	DPI	SMI	Nebulizer
SABA	X	X		X
SAMA	X			X
SABA + SAMA			X	X
LABA		X	X	X
LAMA		X	X	X
LABA + LAMA	X	X	X	
ICS	X	X		X
ICS + LABA	X	X		
ICS + LABA + LAMA	X	X		
MCS				X

pMDI, metered-dose inhaler; DPI, dry powder inhaler; SMI, soft-mist inhaler; SABA, short-acting β-agonist; SAMA, short-acting muscarinic antagonist; LABA, long-acting β-agonist; LAMA, long-acting muscarinic antagonist; ICS, inhaled corticosteroid; MCS, mast cell stabilizer.

BRONCHODILATORS

Bronchodilation produced by β-adrenergic agonists, muscarinic antagonists, and methylxanthines is a major component of the pharmacologic management of obstructive airway diseases. Other drugs (e.g., magnesium) have been used clinically for bronchodilation.

β-Adrenergic Agonists

The β-adrenergic agonists mimic the actions of norepinephrine at neuroeffector and synaptic junctions. Norepinephrine is the major neurotransmitter in the sympathetic nervous system; therefore, this class of drugs is referred to as *adrenergic agonists* or *sympathomimetics*. The two major types of adrenergic receptors are the α and β receptors; at least two α and three β receptor subtypes have been identified.

β-Adrenoceptor stimulation relaxes smooth muscles via cyclic-3′5′-adenosine monophosphate (cAMP)-dependent and cAMP-independent mechanisms.[5] Adrenergic receptor stimulation catalyzes the conversion of adenosine triphosphate (ATP) to cAMP by activating adenyl cyclase, a cofactor in the production of cAMP. The increase in cAMP triggers the intracellular events that mediate

TABLE 144-2 Age–Device Guidelines

Device	Age
pMDI	≥5 years <5 years, spacer or VHC with face mask
DPI	≥4 years
Spacer or VHC	≥4 years <4 years, VHC with face mask
Nebulizer	Infants: SVN with face mask or hood ≤3 years: SVN with face mask ≥3 years: SVN with mouthpiece ≥5 years: Breath-actuated nebulizer All ages unable to use pMDI with VHC and face mask

pMDI, metered-dose inhaler; DPI, dry powder inhaler; VHC, valved holding chamber; SVN, small-volume nebulizer.

TABLE 144-3 Adrenergic Agonists

	Receptor Activity			Dosage Forms						
Agent	α	β_1	β_2	Duration[a]	pMDI	DPI	Neb	SC	SMI	Oral
Albuterol		Slight	+	Short	√	√	√			√
Arformoterol		Slight	+	Long			√			
Epinephrine	+	+	+	Short				√		
Formoterol		Slight	+	Long			√			
Indacaterol		Slight	+	Very long		√				
Levalbuterol		Slight	+	Short	√		√			
Metaproterenol		Slight	+	Short						√
Olodaterol		Slight	+	Very long					√	
Pirbuterol[b]		Slight	+	Short	√					
Racepinephrine[c]	+	+	+	Short			√			
Salmeterol		Slight	+	Long		√				
Terbutaline		Slight	+	Short				√		√
Vilanterol		Slight	+	Very long		√				

pMDI, metered-dose inhaler; DPI, dry powder inhaler; Neb, nebulizer solution; SC, subcutaneous.

[a] Duration: short, 1–6 h; long, 8–12 h; very long, 24 h.

[b] Breath-activated autohaler; contains chlorofluorocarbons; last date for sale in the United States was December 31, 2012.

[c] Nonprescription product.

pulmonary and extrapulmonary responses. β-Adrenoceptor stimulation also activates large-conductance, calcium-activated potassium channels in plasma membranes independent of cAMP.

The β-adrenergic agonists (Table 144-3) are indicated in the treatment of bronchospasm associated with acute and chronic asthma, bronchitis, emphysema, exercise, and other obstructive pulmonary diseases. Selection of a specific agent and route of administration depends on underlying patient risk factors and the receptor specificity of the drug.

Pharmacology

Adrenergic receptors are G-protein cell surface receptors. Adrenergic agonist binding to the β_2-adrenergic receptor activates Gs subtype proteins.[6] Gs subtype proteins stimulate adenylyl cyclase and activate cAMP-dependent protein kinase (PKA). PKA phosphorylates proteins involved in intracellular calcium regulation and sensitivity. Adrenergic receptor stimulation produces a wide range of functional responses, depending on the effector organ and the specific receptor.[7] Although bronchial smooth-muscle relaxation results from β_2-adrenergic receptor stimulation, none of the currently marketed agonists is completely specific for β_2-adrenergic receptors. The α-adrenergic receptor is generally associated with constrictor/contractor responses, including constriction of arteries and veins and contraction of the uterus, radial and sphincter muscles of the iris, urinary bladder, and stomach sphincters. β_1-Adrenergic receptor stimulation increases heart rate, atrial and ventricular contractility, and cardiac conduction velocity. Effects from β_2-adrenergic receptor stimulation include relaxation of bronchial and uterine smooth muscle, dilatation of arteries and veins, and several metabolic effects, including glycogenolysis, gluconeogenesis, and induction of hepatic pancreatic β-cell secretion.

Structure–Activity Relationships

The parent compound for the adrenergic agonists, phenylethylamine, consists of a benzene ring and an ethylamine side chain. Substituents can be added to the α or β carbons of the ethylamine side chain, the terminal amine group, or one or more of the carbons in the aromatic ring.[8] The addition of hydroxyls at positions 3 and 5 of the aromatic ring (e.g., metaproterenol and terbutaline) promotes oral bioavailability. Large substituents added to the amino group promotes β_2-adrenergic receptor selectivity and favors a long duration of action (e.g., arformoterol, formoterol, indacaterol, olodaterol, salmeterol, vilanterol).

At least two theories have been proposed to explain the long duration of action of the long-acting and ultra-long-acting β_2-adrenergic agonists (LABAs).[9,10] The *exosite theory* states that a portion of the large side chain on the terminal amine binds to a site separate from, but close to, the β_2-adrenergic receptor, keeping the active portion of the structure available for binding and rebinding to the β_2-adrenergic receptor. The *diffusion mucokinetic model* states that the plasma membrane serves as a drug reservoir. However, neither theory fully explains the long duration of action of the long- and ultra-long-acting β_2-adrenergic agonists, suggesting additional mechanisms.

Enantiomers

Albuterol and formoterol are 1:1 mixtures of (R)- and (S)-enantiomers. The therapeutic effect of albuterol comes from the (R)-enantiomer; the (R)-enantiomer is marketed separately as levalbuterol. Early in vitro studies suggested that (S)-albuterol might antagonize the effects of (R)-albuterol, but levalbuterol has not been demonstrated to be clinically superior to racemic albuterol.[11] The (R)-formoterol enantiomer, marketed as arformoterol, is 1000-fold more potent in β_2-receptor binding affinity than the (S)-enantiomer.[12] The racemic mixture is marketed as formoterol. Formoterol and arformoterol are equally effective bronchodilators with similar side effect profiles.[13]

Drug Delivery

The β-adrenergic agonists may be administered systemically or by inhalation; however, not all drugs are marketed in every dosage form (Table 144-1). Systemic dosage forms include oral (i.e., tablets, syrups), subcutaneous, and intravenous preparations. Systemic administration decreases the β_2-adrenergic receptor selectivity of the drug due to exposure to various metabolic enzymes, including catechol-o-methyl transferase, monoamine oxidase, and sulfatase. These enzymes change the chemical structure of the drug, decreasing the β_2-adrenergic receptor selectivity.

Inhaled β-adrenergic agonists are available in several dosage forms, including wet aerosols, aerosols from MDIs, and dry powder forms. Historically, nebulized drug delivery was standard practice for children and for emergency treatment of asthma exacerbations, hospitalized patients, and severely obstructed patients. Comparative data are limited, but outcomes are similar for drug delivery with MDI plus spacer drug delivery and nebulization.[14,15] Nebulized drug delivery is labor intensive; significant cost savings can be realized, without sacrificing efficacy, by using MDIs coupled with spacer devices.

Clinical Use

The β_2-adrenergic agonists remain first-line drugs in the treatment of both asthma and chronic obstructive pulmonary disease (COPD).[16,17] In asthma, the short-acting inhaled β_2-adrenergic agonists are preferred for treating acute symptoms and for preventing exercise-induced bronchospasm. The subcutaneous route of administration is generally reserved for patients unresponsive to frequent, high-dose, inhaled β_2-adrenergic agonists; uncooperative patients; or patients too severely dyspneic to inhale the dose. Subcutaneous or parenteral administration should not be used in patients with angina or a recent history of myocardial infarction. Oral adrenergic agonists may be appropriate for children too young to cooperate with inhaled drug administration; sustained-release, oral adrenergic agonists decrease nocturnal symptoms, but they are less effective than LABAs.

In COPD, β_2-adrenergic agonists provide modest symptomatic relief and improvement in pulmonary function. LABAs are standard bronchodilator therapy for patients with moderate and severe COPD. The value of subcutaneous drugs and high-dose, short-acting bronchodilators in the management of COPD remains indeterminate.

The intensity and duration of response to β_2-adrenergic agonists is dose and frequency dependent. For patients with asthma, higher doses result in incrementally greater bronchodilation. The dose–response relationships are less well defined for COPD.

The dose–response curve in asthma led to the development of intensive inhaled β_2-adrenergic agonist drug regimens for the treatment of severe, acute exacerbations. Typically, the nebulized drug is administered every 20 min for three to six doses; some patients respond better to continuous nebulized drug delivery. These regimens are generally well tolerated, although cardiac stimulation is common.

The LABAs are add-on agents for patients with moderate or severe asthma when usual doses of inhaled corticosteroids are inadequate and for patients with moderate or severe COPD. The LABAs are also alternate add-on agents for patients with symptoms of nocturnal asthma. The LABAs play no role in the treatment of an acute asthma or COPD exacerbation; all patients should have a short-acting inhaler and should be instructed on how and when to use each type of β_2-adrenergic agonist. International guidelines recommend single maintenance and reliever therapy (SMART) with a combination of a quick onset long duration LABA and inhaled corticosteroid for management of patients with moderate to severe asthma.[18] The combination of formoterol, a long-acting β-adrenergic agonist with a rapid onset of action and long duration of action and inhaled corticosteroid has been documented to lower the risk of asthma exacerbations.[19,20]

Tolerance, that is, receptor subsensitivity or tachyphylaxis, is a decreased response to receptor stimulation. Regular use of either short- or long-acting β_2-adrenergic agonists leads to tolerance of both the nonbronchodilator and bronchodilator effects of the β_2-adrenergic agonist.[21] Tolerance to the nonbronchodilator effects of the β_2-adrenergic agonists, including tremor, tachycardia, QT_c prolongation, hypoglycemia, hypokalemia, and vasodilation, has been recognized for many years. Tolerance to the bronchodilator effects of the β_2-adrenergic agonists develop rapidly with quick recovery following discontinuation of the drug.[22] Receptor downregulation mediated by β-arrestin and G protein–coupled regulatory kinase likely mediates tolerance to the β_2-adrenergic agonists.[23]

Safety

The β_2-selective adrenergic agonists produce less cardiovascular toxicity than do the nonselective agents, but because β_2-adrenergic receptors are expressed in cardiac tissues and some innate immune cells (e.g., eosinophils, mast cells), β_2-selectivity does not protect from all adverse events.[6]

Biochemical abnormalities associated with the β_2-adrenergic agonists include hyperglycemia, hyperinsulinemia, lipolysis, hypokalemia, hypomagnesemia, and lactic acidosis.[7] These side effects are most pronounced with parenteral and oral drug administration; they are minimal with usual doses of inhaled agents.

β_2-Adrenergic agonists cause dose- and route-dependent hyperglycemia by stimulating glycogenolysis and gluconeogenesis and suppressing glucose clearance.[24] Hyperglycemia may be clinically most important in asthmatic patients with diabetes mellitus or during pregnancy. β_2-Adrenergic agonists increase plasma insulin by directly stimulating pancreatic islet cells; indirect increases occur secondary to the hyperglycemic response. β_2-Adrenergic agonists induce the release of free fatty acids from adipose tissue. Although hyperinsulinemia and high concentrations of free fatty acids have been linked with cardiovascular morbidity and mortality, tolerance minimizes these effects. β_2-Adrenergic receptor stimulation also induces muscle glycogenolysis, increasing lactate production.

The β_2-Adrenergic agonists induce hypokalemia by increasing cellular uptake of potassium via direct stimulation of cell membrane Na^+/P^+-ATPase.[25] β_2-Adrenergic receptor stimulation induces the cellular uptake of magnesium; hypomagnesemia may induce arrhythmias or worsen symptoms of coronary artery disease. Other adverse β_2-adrenergic agonist effects include (1) an increased baseline tremor by creating an imbalance in fast- and slow-twitch muscle groups; (2) tachycardia by direct chronotropy and through reflex peripheral vasodilatation and decreased venous return; and (3) central nervous symptoms, such as appetite suppression, headache, nausea, and sleep disturbances.[7] The nervousness reported by many patients is probably a response to the peripheral tremors, rather than a result of direct stimulation of the central nervous system.

β-Adrenergic agonist use has increased coincident with the increase in asthma morbidity and mortality in the United States and other countries. The first linkage between β-adrenergic agonists and asthma mortality was identified during the 1960s when the newly marketed, nonselective, short-acting β-adrenergic agonist isoproterenol was associated with an increase in asthma morbidity and mortality in the United Kingdom. In 2006, two studies associated LABA use with an increased risk of death in patients with asthma.[26,27] In 2005, the U.S. Food and Drug Administration (FDA) began requiring that labeling for all LABAs include a black box warning regarding the increased risk of asthma-related death. In 2010, the FDA released new safe-use requirements for LABAs.[28] The FDA requires (1) that LABAs be used in combination with an asthma controller medication, and only in patients whose asthma is poorly controlled despite controller medications; (2) that LABAs be used for the shortest duration of time needed to achieve control and then be discontinued, if possible; and (3) that combination inhaled corticosteroid–LABA products be used for children and adolescents.[28] In 2011 the FDA required manufacturers of LABAs to conduct postmarketing safety trials for LABAs in the treatment of asthma.[29] Combined analysis of these safety trials found no significant increase in risk with combined LABA and corticosteroid therapy.[30] In 2017 the FDA removed the black box warning for combination LABA-corticosteroid medications; the black box warning for single-entity LABA medications remains.[3] The mechanism of increased risk of LABAs as single-entity treatment of asthma is unclear, although it may be related to β_2-adrenergic receptor downregulation and desensitization.

Anticholinergics

Atropine, scopolamine, and other naturally occurring antimuscarinic alkaloids from plant extracts have been used for thousands of years to relieve respiratory symptoms in humans with airway diseases. Historically, clinical use of atropine and atropine-like agents has been limited by side effects, including dry mouth and skin, tachycardia, meiosis, and difficulty urinating and mentating. Six synthetic atropine derivatives (ipratropium, tiotropium, aclidinium, umeclidinium, glycopyrrolate, and revefenacin), which have more favorable side effect profiles, are available for management of COPD.

Pharmacology

Anticholinergics, also known as parasympatholytics or antimuscarinics, reversibly compete with acetylcholine at muscarinic receptors. Acetylcholine is the predominant airway parasympathetic neurotransmitter. Three of the five known muscarinic receptor subtypes (M_1, M_2, and M_3) are located on airway smooth muscle, nerves, glands, and innate lymphoid cells (eosinophils, macrophages, lymphocytes, neutrophils).[32] Acetylcholine receptor binding activates adenylyl cyclase and phospholipase C and opens potassium channels, effecting bronchoconstriction, goblet cell metaplasia and increased mucus secretion, airway hyperreactivity, inflammation, airway smooth muscle thickening, and extracellular matrix deposition.[33] M_1 and M_3 muscarinic receptors are excitatory; airway M_2 receptors are inhibitory though with minimal effect on airway smooth muscle contraction. M_1 muscarinic receptors, located in airway epithelial cells and ganglia, regulate epithelial cell electrolyte and water secretion. M_3 muscarinic receptors, the primary receptor subtype in airway smooth muscle and submucosal glands, regulate airway smooth muscle and mucus secretion.[33]

Five of the six currently FDA-approved anticholinergic medications for management of obstructive lung diseases (ipratropium bromide, tiotropium bromide, aclidinium bromide, umeclidinium bromide, and glycopyrrolate) are quaternary ammonium compounds. Revefenacin, the newest anticholinergic, is a biphenyl carbamate tertiary amine. Shared properties include minimal absorption following oral inhalation, inability to penetrate the blood–brain barrier, similar binding affinities for M_1, M_2, and M_3 muscarinic receptors, and longer M_3-drug complex dissociation half-lives than M_1-drug complex and M_2-drug complex dissociation half-lives.

Ipratropium bromide, the only marketed short-acting anticholinergic, has a shorter M_3-drug complex dissociation half-life than the long-acting anticholinergics.[34–36] Bronchodilation following inhalation of ipratropium bromide occurs within 15 min with peak effect in 1 to 2 h.[37] Inhalation of the long-acting anticholinergics typically produces bronchodilation within 1 h with prolonged duration of action.[37–41] Tiotropium bromide, umeclidinium bromide, and revefenacin are approved for once-daily administration. Aclidinium bromide and glycopyrrolate are approved for twice-daily administration. Differences among the long-action anticholinergics in terms of muscarinic subreceptor affinities and receptor–drug complex dissociations are measurable, although the clinical relevance is not well described.

Drug Delivery

Ipratropium bromide is available in the United States as a HFA MDI. Tiotropium bromide, aclidinium bromide, umeclidinium bromide, and glycopyrrolate are available in the United States as DPIs. Additional dosage formulations include soft-mist aerosol inhaler (tiotropium bromide) and solutions for nebulization (ipratropium bromide, revefenacin, and glycopyrrolate). Various combination products with short-acting and long-acting bronchodilators and corticosteroids are marketed in multiple dosage formulations.

Clinical Use

Ipratropium bromide, tiotropium bromide, aclidinium bromide, umeclidinium bromide, glycopyrrolate, and revefenacin are FDA-approved for the management of patients with COPD. The long-acting anticholinergics improve quality of life and reduce hospitalizations due to COPD exacerbations. The Global Initiative for Chronic Obstructive Lung Disease (GOLD) 2022 Report recommends monotherapy with long-acting anticholinergics for the initial management of patients with fewer symptoms and greater exacerbation risks, and as monotherapy or combination therapy with long-acting β-adrenergic agonists for patients with more symptoms, regardless of the exacerbation risk.[17] The GOLD 2022 Report recommends long-acting anticholinergics for follow-up pharmacologic therapy as alternative or add-on therapy.[17]

Tiotropium bromide as the soft mist inhaler Spiriva was approved by the FDA in 2015 for maintenance therapy of asthma in adults and children 12 years of age and older; the approved age range was subsequently lowered to 6 years of age and older. No other drug delivery system or anticholinergic drug is FDA-approved for the management of asthma. A systematic review concluded that the addition of tiotropium bromide to a combination of long-acting β_2-adrenergic agonists and inhaled corticosteroids reduced the need for rescue oral corticosteroids.[42]

International guidelines recommend the addition of the short-acting anticholinergic ipratropium bromide to short-acting β-adrenergic agonists in the emergency management of adults with moderate to severe asthma exacerbations.[18] Compared with the β-adrenergic agonists, anticholinergics have a slower onset of action and less effect on lung function and should not be used in place of short-acting bronchodilators.[43] A systematic review concluded that patients with severe asthma exacerbations treated with a combination of β-adrenergic agonist and anticholinergic were less likely to be admitted to the hospital; the effect was less in patients with mild to moderate asthma exacerbations.[44] Any such use of an anticholinergic in the United States is off-label and not FDA-approved.

Safety

Consistent with their very low systemic bioavailability, the inhaled anticholinergics are remarkably free of side effects. Class effects with inhaled anticholinergics include mild dry mouth, constipation, and throat irritation. The inhaled anticholinergics do not change mucus viscosity or transport, pulmonary hemodynamics, ventilation–perfusion matching, oxyhemoglobin saturation, heart rate, or urinary flow; however, blurred vision and pupillary dilation may occur if any drug inadvertently contacts the eye. Anticholinergics should be used with caution in patients with narrow-angle glaucoma, prostatic hyperplasia, or bladder neck obstruction.

Dose modifications for renal or hepatic impairment are not required for ipratropium bromide, tiotropium bromide, and aclidinium bromide. Ipratropium bromide is partially metabolized to inactive ester hydrolysis products. Tiotropium bromide undergoes minimal hepatic metabolism via CYP2DC and CYP3A4. Plasma esterases rapidly hydrolyze aclidinium bromide to inactive metabolites. Glycopyrrolate, excreted in the urine and bile, should be used with caution in patients with renal impairment (Clcr <30 mL/min/1.73 m^2). Revefenacin, hepatically metabolized to an active carboxylic acid, should not be used in patients with any degree of hepatic impairment.

Cardiovascular risks with inhaled anticholinergics in patients with COPD have been identified, but absent quality long-term data, the issue remains unresolved.[45] A 2011 meta-analysis of 17 randomized controlled trials of tiotropium bromide delivered with the Respimat soft-mist inhaler identified a statistically significant increase in cardiovascular events, including stroke, myocardial infarction, and death with long-term (≥30 days) tiotropium bromide.[46] Tiotropium bromide delivered with the Respimat soft-mist inhaler appears to be safe in patients with asthma.[47] A trial directly comparing tiotropium dry powder and fine-mist inhaler safety in patients with COPD revealed no significant differences in either safety or efficacy.[48] No increased risk for major cardiovascular events in patients with COPD has been identified for aclidinium bromide, umeclidinium bromide, glycopyrrolate, or revefenacin.[49–52] However, until adequate long-term safety data are available, long-acting anticholinergics should be used with caution in patients with unstable ischemic heart disease, history of myocardial infarction, left ventricular failure, history of arrhythmias including long QT syndrome, narrow-angle glaucoma, prostatic hyperplasia, and bladder-neck obstruction.

Drugs with anticholinergic properties are used to manage a wide range of medical conditions including allergies, arrhythmias, depression, diarrhea, emesis, muscle spasms, Parkinson disease, and psychosis. Concomitant use of drugs with anticholinergic properties and anticholinergic bronchodilators may increase the risk of anticholinergic side effects.

■ Methylxanthines

Methylxanthines have been used to treat pulmonary disease for more than 100 years.[53] General use of methylxanthines became widespread in the 1930s; contemporary use is more limited due to the availability of more effective and safer medications. Theophylline and aminophylline, the ethylenediamine salt of theophylline, are used to treat asthma and COPD. Theophylline may also have a role in therapy of obstructive sleep apnea, apnea of prematurity, and airway obstruction secondary to pulmonary edema.

Pharmacology

Potentially beneficial therapeutic effects of theophylline include bronchial smooth-muscle relaxation, enhanced mucociliary transport, inhibition of mediator release, suppression of permeability edema, decreased pulmonary hypertension, increased right ventricular ejection fraction, improved diaphragmatic contractility, and central stimulation of ventilation.

Methylxanthines have direct bronchodilator and immunomodulatory properties; however, despite having been marketed and studied for decades, the precise molecular mechanism of action is not known. Multiple molecular mechanisms have been proposed, including competitive adenosine receptor inhibition (A_1, A_2, and A_3 receptors), nonselective phosphodiesterase (PDE) inhibition, GABA receptor modulation, activation of ryanodine-sensitive calcium channels, activation of histone deacetylases (HDACs), reduced expression of inflammatory genes, promotion of neutrophil and T-lymphocyte apoptosis, and inhibition of poly(ADP-ribose)polymerase-1 (PARP-1).[54,55] Nonselective PDE inhibition and adenosine receptor antagonism are the most established of the proposed molecular mechanisms of action at clinically relevant plasma drug concentrations.[54,55]

PDEs hydrolyze cAMP and cyclic guanine monophosphate (cGMP) to inactive 5′ monophosphates; inhibition of PDE increases intracellular concentrations and, therefore, the activity of these secondary messengers, resulting in airway smooth-muscle relaxation and bronchodilation. However, methylxanthine PDE inhibition is weak and concentration dependent, with minimum inhibition seen at clinically relevant serum concentrations.[54] Adenosine is a nucleoside signaling molecule. Adenosine receptor antagonism regulates airway smooth muscle, blocks adenosine-induced mast cell degranulation, and activates HDAC enzymatic activity, inhibiting transcription of proinflammatory cytokines. These anti-inflammatory and immunomodulatory effects are observed at clinically achievable serum drug concentrations.[54]

The anti-inflammatory effect of methylxanthines appears to be qualitatively different than that of corticosteroids. Corticosteroids recruit HDACs to sites of active inflammatory gene transcription. The HDACs then inhibit histones, inhibiting inflammatory gene transcription.[56] Methylxanthines, independent of phosphodiesterase and adenosine activity, induce HDAC epithelial cell and macrophage activity.[56] The combination of corticosteroids and methylxanthines may be synergistic.

Structure–Activity Relationships

Xanthine structure substituents determine methylxanthine pharmacology.[57] Theophylline and aminophylline are 1,3-dimethylxanthines. Other methylxanthines, including theobromine (3,7-dimethylxanthine) and caffeine (1,3,7-trimethylxanthine), differ in the positions of the methyl substituents on the xanthine molecule. Dyphylline is a synthetic 7-(2,3-dihydroxypropyl)-theophylline. N-1 substituents are important for adenosine antagonism, whereas N-3 substituents augment bronchodilator activity. Substituents at N-7 decrease bronchodilator potency; substituents at N-9 decrease the potency of the xanthine. C-8 substituents determine adenosine receptor subselectivity.

Drug Delivery

Three methylxanthines are available in the United States: theophylline, aminophylline, and dyphylline. Dosage forms for theophylline include extended-release tablets and capsules, oral solution, oral elixir, and intravenous solution. Aminophylline, the ethylenediamine salt of theophylline, is available as an intravenous solution. Dyphylline is available as immediate release tablets and oral solution.

Clinical Use

Methylxanthines are FDA approved for the treatment of reversible airway obstruction associated with chronic asthma or other chronic lung disease. Concerns regarding the relative efficacy and safety of the methylxanthines in comparison to other bronchodilators and long-term control medications have relegated methylxanthines to alternative therapy status for both asthma and COPD. Caffeine is the preferred methylxanthine for the treatment of apnea of prematurity.[58]

The GOLD guidelines identify oral theophylline as an alternative maintenance bronchodilator.[17] The current Global Initiative for Asthma (GINA) guidelines recommend low-dose theophylline as an add-on controller medication for adolescents and adults with step 3 and step 4 asthma inadequately controlled on inhaled glucocorticoids alone and as an add-on controller for adolescents and adults with step 5 asthma inadequately controlled on dual therapy.[18] The current National Asthma Education and Prevention Program (NAEPP) guidelines recommend theophylline as an alternate medication for patients with mild persistent asthma, or as an alternate adjunctive therapy in combination with inhaled corticosteroids.[16] Neither the GINA nor the NAEPP guidelines recommended theophylline for the treatment of acute asthma exacerbations.[16,18] The previously accepted therapeutic range for theophylline (10–20 mg/L) was based on early dose–bronchodilator response studies and is no longer considered state of the art.[55,59] The current NAEPP asthma guidelines recommend a lower target therapeutic range for theophylline (5–15 mg/L).[16] The rationale for lowering the target serum theophylline range includes improved understanding of the dose–bronchodilator response and recognition of the greater risk of adverse drug reactions at serum theophylline concentrations greater than 15 mg/L. Nonbronchodilator effects, including immunomodulatory effects and effects on diaphragmatic activity are associated with lower serum concentrations (<10 mg/L).[60,61]

Safety

Adverse effects of methylxanthines are generally attributed to PDE inhibition (nausea, vomiting, diarrhea, headache, and increased acid secretion and gastrointestinal reflux) and adenosine receptor antagonism (diuresis, cardiac arrhythmias and seizures).[55] Other adverse effects include irritability and insomnia. The caffeine-like adverse effects (nausea, vomiting, diarrhea, nervousness, insomnia, headache) are generally associated with serum theophylline concentrations greater than 15 mg/L.[62] The more life-threatening adverse effects (ventricular arrhythmias and seizures) are generally associated with serum theophylline concentrations greater than 40 mg/L, although these adverse effects may occur at much lower serum concentrations.[62]

Theophylline is metabolized primarily by cytochrome P450 (CYP1A2) enzymes, making it susceptible to numerous drug–disease and drug–drug interactions.[63] Hyperthyroidism and cystic fibrosis decrease serum theophylline concentrations by unknown mechanisms. Polycyclic aromatic hydrocarbons in tobacco smoke, and medications such as rifampin, phenytoin, antivirals, and barbiturates, induce cytochrome P450 enzymes, reducing serum theophylline concentrations. Macrolide and quinolone antibacterials, fluvoxamine, fluconazole, ketoconazole, and cimetidine inhibit cytochrome P450 enzymes, increasing serum theophylline concentrations.

Medical conditions that directly impair hepatic function (e.g., cirrhosis, viral hepatitis), cause passive hepatic congestion (e.g., congestive heart failure, cor pulmonale), or induce interferon (e.g., acute viral illness or pneumonia) result in increased serum theophylline concentrations.[62] CYP1A2 single polymorphisms may influence methylxanthine metabolism but are not well described. Methylxanthine metabolism is markedly reduced in neonates, increased in children and adolescents, and reduced in adults 65 years of age and older.[63]

Given the narrow therapeutic window, multitude of drug and disease interactions, and wide interpatient variability, it is important to routinely monitor serum theophylline concentrations. The mid-dosing interval serum concentration should be assessed 3 to 5 days after initiating theophylline or modifying the dose and any time theophylline toxicity is suspected.[16]

■ Other Bronchodilators

Ancillary drugs sometimes used as bronchodilators include magnesium sulfate and inhaled diuretics.

Magnesium Sulfate

The bronchodilatory mechanism of action of magnesium has not been definitively identified. Several actions have been proposed, including transient blockade of N-methyl-D-aspartate–gated calcium channels, decreasing smooth-muscle intracellular calcium, and inhibition of mast cell degranulation and acetylcholine release.[64]

Several systematic reviews of trials of inhaled and intravenous magnesium sulfate in the management of adults and children presenting to emergency departments with severe acute exacerbations of asthma have been published.[65–69] In general, patients with severe exacerbations demonstrate small improvements in pulmonary function following administration of inhaled or intravenous magnesium sulfate when added to standard therapy. However, the small numbers of patients studied, differences with exacerbation severity, patient age, dosage, primary outcomes, and concurrent therapy make the data difficult to interpret. The most recent, well-done clinical trial failed to demonstrate any salutary effect of inhaled magnesium on the need for admission or any secondary outcome measures in children with asthma.[70] Potential adverse effects include hypotension with rapid infusion, muscle weakness, respiratory depression, and cardiac conduction abnormalities. The current GINA guidelines recommend considering intravenous magnesium sulfate in the management of severe acute asthma exacerbations in adults not responding to initial treatment and nebulized isotonic magnesium sulfate in the first hour of treatment of acute severe asthma exacerbations in children 2 and older.[18]

Inhaled Diuretics

Inhaled diuretics (e.g., furosemide) may act upon the airways through a variety of mechanisms to achieve bronchodilation, reduce mucosal inflammation, or interrupt sensory nerve reflex responses to irritants.[71] Data regarding the clinical efficacy of inhaled diuretics in the treatment of acute and chronic asthma are limited. A meta-analysis of six randomized controlled trials (with only 78 total patients) found that adjunctive inhaled furosemide in doses of 20 to 40 mg in adults and 1 mg/kg or 10 mg/m^2 in children significantly improved airflow obstruction with no adverse effects.[72] Additional information from well-designed clinical trials is needed before use of inhaled diuretics can be recommended for the treatment of acute exacerbations or chronic management of asthma.

ANTI-INFLAMMATORY AGENTS

Corticosteroids are the mainstay of current anti-inflammatory regimens; other agents in clinical use include mast cell stabilizers, leukotriene receptor antagonists, and leukotriene formation inhibitors.

■ Corticosteroids

Corticosteroids are cortisol-like drugs that influence metabolic pathways and have an anti-inflammatory effect. By reducing airway inflammation, corticosteroids have long been known to be useful in the management of asthma; their role in the management of COPD has been increasingly recognized.

Pharmacology

Cortisol is produced by the adrenal cortex and regulated via the hypothalamic–pituitary axis in response to physical and emotional distress. The usual daily secretion of cortisol is approximately 7 mg/m^2/d in men and 5 to 6 mg/m^2/d in women; up to 500 mg/d can be secreted during periods of severe stress.[73,74] Corticosteroids stimulate and inhibit DNA transcription in cells with glucocorticoid receptors, which are widespread throughout the body.

Glucocorticoids diffuse across cellular membranes to bind inactive glucocorticoid cytoplasmic receptors; these activated glucocorticoid-receptor complexes translocate to the nucleus and bind to specific glucocorticoid response elements of the gene, influencing gene transcription.[75] Increased gene transcription increases expression of β_2-adrenergic receptors, increases the production of anti-inflammatory mediators, and decreases the production of inflammatory mediators. The clinical effects of glucocorticosteroids are delayed for several hours following administration, reflecting the time needed to influence gene transcription. In the airways, glucocorticosteroids increase the number and responsiveness of β_2-adrenergic receptors, decrease mucus production, decrease bronchial hyperresponsiveness, decrease the number of mucosal mast cells, enhance eosinophil apoptosis, and decrease airway edema. Glucocorticosteroids are inactivated by hepatic metabolism, with a clearance rate approximately the same as liver blood flow; beclomethasone dipropionate, ciclesonide, and their metabolites are also inactivated by blood esterases.

The inhaled glucocorticoids (beclomethasone dipropionate, budesonide, ciclesonide, fluticasone furoate, fluticasone propionate, mometasone furoate) have different physicochemical properties (potency, receptor-binding affinity, protein binding, lipophilicity, oral bioavailability, pulmonary bioavailability, systemic clearance, volume of distribution, and half-life).[76] Physicochemical properties that enhance inhaled glucocorticosteroid efficacy include high receptor-binding affinity, high pulmonary bioavailability, and long pulmonary retention time. Physicochemical properties that enhance safety include low oropharyngeal deposition, high protein binding, rapid systemic clearance, and conversion of inactive prodrug to active drug in the lungs. Since inhaled glucocorticosteroids are marketed and prescribed in relatively equipotent doses, potency is not an important differentiating characteristic as other physicochemical characteristics.

Data regarding the relative clinical benefits of inhaled corticosteroids with different physicochemical characteristics are limited. However, physicochemical characteristics may influence drug safety. For example, oropharyngeal side effects (dysphonia, oral candidiasis) may be minimized by using drug delivery systems that generate a greater proportion of small particles (<5 μm) and with administration of prodrugs that are converted in the lungs to the active drug.[77] DPI particle size depends on the specific device and the patient-generated inhalation flow rate; hydrofluoroalkane MDIs tend to generate a greater proportion of smaller particles. Beclomethasone 17,21-dipropionate is hydrolyzed in the lungs to the more active drug, beclomethasone 17-monopropionate. Ciclesonide is hydrolyzed in the lungs from the inactive parent drug to the active drug, desisobutyryl-ciclesonide.

The risk of systemic adverse effects may be minimized by using inhaled corticosteroids with low systemic bioavailability, high protein binding, rapid systemic clearance, and increased pulmonary residence time. Ciclesonide, fluticasone, and mometasone undergo rapid first-pass hepatic metabolism, resulting in very low ($<1\%$) oral bioavailability. Ciclesonide and mometasone are highly protein bound (99%). Drugs with a higher lipophilicity and drugs that undergo lipid conjugation have a longer pulmonary residence time. Mometasone furoate, beclomethasone dipropionate, fluticasone furoate, and fluticasone propionate have higher lipophilicity than fluticasone propionate, ciclesonide, and budesonide.[76]

Clinical Use

Corticosteroids are the cornerstone of therapy in the treatment of asthma. The role of glucocorticoid therapy in COPD is more limited.

Asthma The role of airway inflammation in asthma is well established, and high-dose systemic (parenteral or oral) corticosteroids are standard therapy for patients experiencing severe acute exacerbations of asthma.[16,18,78] Parenteral administration of corticosteroids is often used preferentially due to the inability of some patients to swallow medications while in respiratory distress or because of lack of oral access after intubation. The time to initial response, as evidenced by augmentation of FEV_1 with bronchodilator administration, begins as early as 1 hour after corticosteroid administration; maximal response is achieved in 8 to 12 h. Parenteral methylprednisolone is the corticosteroid of choice, due to its lower mineralocorticoid and greater glucocorticoid effects than hydrocortisone.

The combination of an inhaled corticosteroid and a long-acting bronchodilator is better than either agent alone at improving lung function and preventing asthma exacerbations; in patients with moderate to severe asthma, such a combination of low-dose inhaled corticosteroid with a LABA appears equally effective as high-dose inhaled corticosteroid alone.[16,18] Given the concerns regarding the safety of LABAs (see above) as monotherapy in asthma, the FDA recommends that an inhaled corticosteroid always accompany a LABA in asthma therapy.[28]

Beclomethasone dipropionate, budesonide, ciclesonide, and fluticasone propionate are FDA approved for twice-daily administration. Mometasone furoate is FDA approved for once- or twice-daily administration. Fluticasone furoate is FDA approved for once-daily administration. Poor adherence with inhaled corticosteroid regimens is an ongoing issue. Although data are limited, patients with stable, mild persistent asthma might benefit from once-daily inhaled corticosteroids.[16] Twice-daily dosage regimens are more effective for patients with moderate persistent or severe persistent asthma.[16]

Chronic Obstructive Pulmonary Disease The mechanism underlying the beneficial effects of corticosteroids in COPD is not fully known, but changes in inflammatory gene transcription and modulation of β_2-adrenergic receptor function appear to play a role. The blood eosinophil count is a potentially useful prognostic and theragnostic biomarker in COPD.[79] Thresholds, rather than specific target blood eosinophil counts, are associated with beneficial effect.[80] The GOLD guidelines recommend initial treatment of patients with more symptoms and exacerbations (GOLD grade D) with a combination of inhaled corticosteroid and long-acting β_2-adrenergic agonist if the blood eosinophils are at least 300 cells/μL.[17] For follow-up therapy of patients experiencing exacerbations, the GOLD guidelines recommend a combination of long-acting β_2-adrenergic agonist plus inhaled corticosteroid if the blood eosinophil count is at least 300 cells/μL; or with at least 100 cells/μL if at least two moderate exacerbations or one severe exacerbation requiring hospitalization.[17]

Treatment of patients hospitalized for management of acute COPD exacerbations treated with short-course (5–7 days) systemic corticosteroids is associated with fewer treatment failures, shorter duration of hospitalization, improved lung function (FEV_1), and improved breathlessness.[81] Five-day regimens are as effective as longer regimens (10–14 days) with less risk for significant adverse effects (e.g., hyperglycemia).[82] For hospitalized patients, the GOLD guidelines recommend consideration of short-course oral corticosteroids (prednisone 40 mg daily for 5 days).[17] Oral corticosteroids in the management of acute COPD exacerbations in nonhospitalized patients appear to be effective based although are not currently recommended in some guidelines.[17,83]

Safety

Short-term use (<14 days) of systemic corticosteroids is associated with mild glucose intolerance, fluid retention that may progress to edema and hypertension, proximal muscle weakness (especially with large parenteral doses), and mood alteration. Long-term systemic corticosteroids prolong the short-term effects; in addition, peptic ulcer disease, cataracts, increased risk of infection, and impaired wound healing occur. Truncal obesity, hirsutism, acne, moon-shaped facies, striae, and ecchymoses contribute to a cushingoid appearance. Disruption of bone metabolism predisposes patients to osteoporosis and resultant vertebral and long-bone fractures; inhibition of long-bone growth is the major complication in children receiving systemic corticosteroids. Suppression of the hypothalamic–pituitary–adrenal axis diminishes body cortisol stores, reducing the response to stresses such as trauma, surgery, or infection.

Inhaled corticosteroids are less systemically bioavailable due to poor absorption from the tracheobronchial tree. The most common adverse effect is local irritation of the oropharynx, cough, and bronchospasm. Dysphonia may arise from vocal cord myopathy induced by the corticosteroid, and oral candidiasis (thrush) may occur secondary to suppression of normal oral flora. The risk of dysphonia and thrush are reduced by rinsing the mouth, gargling, and spitting out the rinse water after each use of a corticosteroid inhaler; using a spacer device to decrease deposition of drug particles in the mouth; and keeping the inhaler mouthpiece clean. Inhaled corticosteroids increase the risk of pneumonia in patients with COPD although the absolute risk is low and may depend on the lipophilicity and lung retention properties of the inhaled corticosteroid.[80] The benefits of reduced COPD exacerbations from combined single-inhaler triple therapy (with a LABA, LAMA, and ICS) appear to outweigh this small absolute risk of community-acquired pneumonia.[84,85]

Depending on the bioavailability, dose, and duration of use, inhaled corticosteroids may be associated with the systemic adverse effects typically associated with oral corticosteroids, including adrenal suppression, particularly in children. Inhaled corticosteroids slow bone growth velocity in prepubertal children and reduce ultimate adult height by about 1 to 1.5 cm.[86] High-dose inhaled corticosteroids decrease bone mineral density and increase bone fracture risk, especially in older and postmenopausal women.[86]

Steroid Resistance

Patients with asthma unresponsive to usually sufficient doses of corticosteroids are described as *steroid resistant.* Varying definitions of steroid resistance exist, such as a less than 15% increase in FEV_1 after either oral prednisolone administered for 7 days at a dose of 20 mg daily, or 14 days at a dose of 15 mg daily; or a 2-week trial of 40 mg/d prednisone in bronchodilator-responsive asthmatics.[87,88] Steroid resistance has been associated with bacterial and viral respiratory infections, exacerbations associated with infections, and a high-fat diet and obesity.[89] Steroid resistance must be distinguished from steroid dependency, which is usually defined as the need for systemic corticosteroids to maintain control of asthma.

Steroid resistance may involve reduced metabolism of oral corticosteroids to the active compound or accelerated drug clearance. An impaired cellular response to corticosteroids has been observed in steroid-resistant asthmatics, and altered receptor binding or the presence of antilipocortin antibodies may contribute to the phenomenon. Aberrant microRNA 21 (miR-21) and interleukin 1β responses may contribute to steroid-resistant airway inflammation.[89]

■ Corticosteroid-sparing Agents

Chronic systemic corticosteroid therapy required for the treatment of severe airflow obstruction often results in numerous side effects. Therefore, many anti-inflammatory agents have been evaluated in an effort to identify alternatives to systemic corticosteroid therapy.[90,91] However, wide variability exists among studies in their assurances of proper inhaler technique, dose and frequency of baseline inhaler regimens, and minimization of exposure to known antigens. In addition, most studies have not systematically evaluated and excluded (or otherwise controlled for) the concomitant presence of disorders known to mimic or exacerbate asthma, including vocal cord dysfunction, gastroesophageal reflux, and rhinosinusitis. These methodologic considerations further restrict the limited conclusions to be drawn from these studies.

Methotrexate

From initial observations in patients with rheumatoid arthritis and coexistent asthma, methotrexate therapy appeared to ameliorate both asthmatic and arthritic symptoms. A small number of older studies offer no clear documentation of the clinical efficacy of methotrexate administration in severe, steroid-dependent asthma. Several more recent meta-analyses suggest a small benefit may exist, but use is associated with a significant risk of toxicity. Due to significant side effects, potentially fatal complications, and long-term toxicity concerns, prudence argues for limiting methotrexate administration in severe, steroid-dependent asthmatics to empiric trials in individual patients or investigations in large-scale, controlled clinical trials.

Cyclosporine

Used widely in organ transplantation, cyclosporine inhibits lymphokine synthesis, thereby blocking the activation of T cells. The absence of significant drug interactions with β-adrenergic agonists, corticosteroids, or theophylline makes cyclosporine particularly attractive as an anti-inflammatory agent for use in asthma. However, only one of the three small, double-blind, placebo-controlled studies suggested that cyclosporine increased peak expiratory flow and FEV_1, reduced exacerbations of airway obstruction, or reduced oral prednisolone dosage by more than 60%. Hypertrichosis, hypertension, reversible nephrotoxicity, and a large number of nonspecific side effects limit widespread use of cyclosporine in the management of asthma.

Other Agents

The search continues for anti-inflammatory agents with potential efficacy in asthma. Historically, a broad spectrum of agents has been touted, including gold salts, pooled immunoglobulins, azathioprine, colchicine, dapsone, hydroxychloroquine, ketotifen, nonsteroidal anti-inflammatory agents, inhaled heparin, and anti–tumor necrosis factor agents (both etanercept and infliximab). The original studies purporting the efficacy of these various agents are mainly anecdotal reports, small case series, or early phase studies demonstrating little clinical efficacy. Use of these drugs in obstructive airway disease should be restricted to well-designed, controlled clinical trials.

■ Antibiotic Macrolides

Recently, the role of macrolide antibiotics as anti-inflammatory agents has been recognized and their potential utility in management of a number of pulmonary disorders examined.

Pharmacology

Erythromycin comprises a 14-membered lactone ring, with two attached sugars (cladinose and desosamine). As the first macrolide antibiotic discovered, erythromycin has served as the base compound for this class of drugs.[92,93] Azithromycin (9-deoxo-9 a-aza-9 a-methyl-9 a-homoerythromycin) is formed by substituting a methyl-substituted nitrogen for the position 9a carbonyl group of the aglycone ring, producing an azalide. Substituting a methoxy group for the C-6 hydroxyl group of erythromycin creates clarithromycin (6-O-methylerythromycin). Compared with erythromycin, both of these macrolide derivatives have superior pharmacokinetic and pharmacodynamic properties, including a longer serum half-life, increased tissue penetration and persistence, increased oral bioavailability, and greater Gram-negative antibacterial activity. Tissue concentrations of clarithromycin and azithromycin can exceed serum concentrations by 100-fold.

In the liver, cytochrome P450 3A4 (CYP3A4) metabolizes clarithromycin to an active 14-hydroxy form and six additional products. Clarithromycin and its metabolites are mostly excreted in the bile. However, since about one-third is excreted in the urine, doses should be reduced in patients with creatinine clearances <30 mL/min. In contrast, with hepatic impairment and normal renal function, the consequent reduced metabolism of clarithromycin to the active 14-hydroxy form allows for increased renal excretion of native clarithromycin and obviates dosing modifications. Since azithromycin elimination occurs primarily in the feces as the unchanged drug, with minimal urinary excretion, dosing modifications are unnecessary in renal or hepatic dysfunction.

Traditionally, antibiotic macrolides are prescribed for infections from a variety of Gram-positive bacteria (β-hemolytic streptococci, pneumococci, staphylococci, enterococci), *Haemophilus influenzae*, *Legionella pneumophila*, *Mycoplasma*, mycobacteria, *Chlamydia*, and some rickettsias. Macrolides rarely cause allergic reactions and, therefore, are a common alternative for penicillin-allergic patients.

Macrolides reversibly bind to ribosomes, where they inhibit protein synthesis in several ways.[92,93] They block peptidyl transferase from adding the peptidyl attached to transfer-RNA to the next amino acid, analogous to the activity of chloramphenicol. Macrolides accelerate dissociation of peptidyl-transfer-RNA from ribosomes and also inhibit ribosomal translocation. Since macrolides accumulate within cells, in addition to their antibacterial actions, they can exert numerous anti-inflammatory effects within the respiratory tract, including increasing mucus clearance, inhibiting neutrophil recruitment and activation, promoting neutrophil apoptosis, and decreasing the production of reactive oxygen species and elaboration of cytokines, including interleukins (IL-4, IL-5, IL-8, IL-13) and chemokines (C-X-C motif ligand 2 [CXCL2], and ligand 2 [CCL2], 3 [CCL3], and 4 [CCL4]). These anti-inflammatory actions are believed to mediate the efficacy of macrolides in controlling exacerbations of underlying respiratory diseases.

Clinical Use

Since the first clinical use of erythromycin as an anti-infective agent in the 1950s, over the past decade a new role has emerged for macrolide antibiotics as anti-inflammatory agents, mainly in treatment of chronic suppurative respiratory disorders. In randomized, double-blind, placebo-controlled trials in adults with either non–cystic fibrosis bronchiectasis or COPD, azithromycin (250 mg daily) or erythromycin (400 mg twice daily in bronchiectasis, 250 mg twice daily in COPD) reduced clinical exacerbations and yielded modest improvements in FEV_1 and quality of life.[94,95]

Retrospective analysis of the Acute Respiratory Distress Syndrome Network dataset revealed increased survival and decreased time to successful discontinuation of mechanical ventilation associated with use of a macrolide early in the clinical course of respiratory failure.[96] However, no randomized trials have expressly tested the efficacy of macrolides in acute lung injury. Azithromycin effectively reduces exacerbations and improves FEV_1 in children with cystic fibrosis, although this effect is attributed to antipseudomonal, rather than anti-inflammatory, effects.[97] Macrolides have not been proven effective in infants with viral bronchiolitis.[98,99]

Safety

Since larger macrolide doses produce higher serum concentrations, the incidence of adverse effects increases with increasing doses. Most common are gastrointestinal side effects, specifically abdominal pain and diarrhea, which are usually tolerable. These side effects appear to represent luminal phenomena, while auditory side effects have been attributed to tissue accumulation. Nonetheless, drug-induced, bilateral, sensorineural hearing loss accentuated at the lower frequencies is usually transient and reverses with discontinuation of the macrolide.

Most clinical trials of chronic macrolide therapy that address resistance demonstrate emergence of macrolide-resistant flora. Hepatotoxicity may occur, as manifested by an increase in liver enzymes or cholestasis—findings that should prompt immediate discontinuation of chronic macrolide therapy.

All macrolides may prolong the QT interval, primarily by blocking the outward delayed rectifier potassium channel encoded by the hERG gene. Indirectly, macrolides may also prolong the QT interval by inhibiting the metabolism of other arrhythmogenic drugs metabolized by CYP3A4. The increase in sudden cardiac death associated with erythromycin administration has led to a marked reduction in use of this drug, particularly in the elderly and patients with heart failure. Electrocardiograms to monitor QT prolongation should be considered during chronic macrolide administration.

Clarithromycin, when oxidized by CYP3A4, forms an inactive metabolite/enzyme complex. Clarithromycin is less potent than erythromycin at inhibiting CYP3A4, and azithromycin minimally inhibits CYP3A4. Therefore, dose reductions, clinical assessments, and therapeutic drug level monitoring (when practicable) are necessary with simultaneous administration of drugs metabolized by the CYP3A4, particularly with clarithromycin or erythromycin therapy. The concurrent use of cisapride, pimozide, terfenadine, and astemizole with clarithromycin or erythromycin is contraindicated because of QT prolongation and reported cases of torsades de pointes. Simultaneous therapy with clarithromycin and ergot compounds risks acute ergot toxicity. Numerous other medications metabolized by CYP3A4 (e.g., benzodiazepines, statins, class 1A antiarrhythmic agents, theophylline, carbamazepine, warfarin, sildenafil, colchicine, cyclosporine) should be used cautiously when given with clarithromycin. Furthermore, although these drug–drug interactions are less likely to occur with azithromycin because of less efficacious inhibition of CYP3A4, high doses may, nonetheless, produce clinically significant side effects. Similarly, respiratory patients with hepatic dysfunction, concurrent congestive heart failure, or cor pulmonale may require dose adjustments. Finally, combination of macrolides with statins has been linked to rhabdomyolysis.[93]

Troleandomycin

Since the 1960s, anecdotal clinical observations suggested that the macrolide antibiotic troleandomycin might reduce corticosteroid requirements in patients with severe asthma by decreasing steroid metabolism. However, results from double-blind, randomized trials were mixed, and the weight of evidence suggests that troleandomycin has no clinical effect at relieving airway obstruction or inflammation independent of its effects on corticosteroid metabolism. Troleandomycin has no role in the current therapy of severe, steroid-dependent asthma.

■ Mast Cell Stabilizers

Cromolyn sodium and nedocromil exert anti-inflammatory actions by stabilizing mast cells. This blockade of mast cell degranulation prevents inflammatory mediator release, which is partially responsible for the bronchoconstriction and epithelial injury that are characteristic of asthma. However, these agents remain inferior to inhaled steroids for controlling asthma.[100] In addition, limited commercial availability of these agents hampers current usage, largely supplanted by the oral leukotriene formation inhibitors and receptor antagonists.

Cromolyn Sodium

Cromolyn sodium was the first mast cell stabilizer to be approved for clinical use in asthma and remains in use as a nebulized agent in pediatric asthmatics. MDI formulations are no longer available in the United States and Canada.

Pharmacology Cromolyn sodium potently inhibits inflammatory responses. Cromolyn sodium diminishes early-phase reactions in asthma by blocking the release of intracellular calcium and inhibiting enzymes responsible for mast cell degranulation; cromolyn reduces late phase reactions in asthma by inhibiting production of the enzymes necessary for superoxide generation. Cromolyn sodium may also exhibit tachykinin antagonism, accounting for some of its anti-inflammatory properties. In vitro, cromolyn sodium potentially inhibits the activation of inflammatory cells, antibody-induced granulocyte cytotoxicity, IgE production by atopic cells, and monocyte IgG production.

Clinical Use Nebulized cromolyn sodium (20-mg dose) is a second-line agent for the management of asthma in children 2 to 5 years of age.[16] Cromolyn sodium, alone or in combination with β_2-adrenergic agonists, reportedly improved exercise tolerance, enhanced sleep quality, and reduced asthma exacerbations. Cromolyn sodium prophylaxes against exercise-induced asthma in children, although less efficaciously than β_2-agonists alone.

Safety Cromolyn sodium causes few adverse effects, even after long-term use. Although the efficacy of cromolyn sodium in preventing childhood asthma symptoms remains unclear, its safety record leads to continued use as a second-line agent, in conjunction with β_2-adrenergic agonists, in management of asthma in children.[100]

Nedocromil

Nedocromil also stabilizes mast cells in the bronchial mucosa, but with a broader anti-inflammatory spectrum than cromolyn sodium. Although useful as prophylaxis against asthma exacerbations, nedocromil is not therapeutically efficacious for acute bronchospasm and is currently available only as a DPI in a small number of countries.

Antileukotriene Agents

Leukotrienes are synthesized from arachidonic acid, a fatty acid stored in phospholipids of cell walls. Numerous stimuli, including IgE receptor activation, antigen–antibody interactions, and activation of phospholipase A_2, induce release of arachidonic acid from phospholipids. Arachidonic acid is converted to a variety of products via several unrelated pathways; the 5-lipoxygenase (5-LO) pathway is the pathway of importance in asthma. Leukotriene A_4 (LTA_4) is metabolized by two different pathways to either the nonpeptide LTB_4 or the cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4). LTB_4 recruits and activates inflammatory cells but has no effect on bronchial tone or reactivity. The cysteinyl leukotrienes stimulate smooth-muscle contraction, increase vascular permeability, and enhance bronchial hyperresponsiveness; thus, they have a role in the pathogenesis of asthma.

Leukotriene action may be inhibited by either selective receptor blockade or interference with synthesis. Most clinical experience has been with the LTD_4 receptor antagonists, since LTC_4, LTD_4, and LTE_4 interact with a common family of cysteinyl leukotriene receptors.[101] Inhibition of 5-LO reduces the generation of all leukotrienes.

Clinical Use

Two LTD4 receptor antagonists (montelukast and zafirlukast) and one 5-LO inhibitor (zileuton) are FDA approved and marketed in the United States. The receptor antagonist pranlukast is available only in Japan; zafirlukast is unavailable in Europe. The antileukotriene agents are alternate anti-inflammatory medications for long-term use in children and adults with mild or moderate asthma, including aspirin- or exercise-induced asthma and asthma associated with concomitant allergic rhinitis.[16] Montelukast is FDA approved for children beginning at age 2 years; zafirlukast for children beginning at age 6 years; and zileuton for teenagers beginning at age 12 years and adults. Although less effective than inhaled steroids or LABAs at improving asthma control, antileukotriene agents have fewer side effects and can provide incremental clinical benefit through bronchodilation and symptom reduction.[102] Acute administration of antileukotriene agents has no role in the management of acute asthma exacerbations.[103] Antileukotriene agents have modest salutary effects on airway obstruction, symptoms, and quality of life in patients with COPD, but administration of zileuton does not reduce length of stay in acute exacerbations of COPD.[104,105]

Safety

Montelukast has a black box warning for serious neuropsychiatric events. Montelukast chewable tablets contain phenylalanine and, therefore, are contraindicated in patients with phenylketonuria. The leukotriene receptor antagonists have numerous drug interactions.

Hepatotoxicity has been reported with zileuton, which is contraindicated in patients with active liver disease and in patients with serum transaminase levels exceeding three times the upper limit of normal. Baseline liver function tests should be obtained prior to initiating therapy with zileuton, and patients should be monitored closely for the duration of therapy. Zileuton must be discontinued if serum transaminase levels exceed five times the upper limit of normal.

Immunoglobulin E Antibody

Administration of antibodies directed against immunoglobulin E (IgE) has a role in management of pulmonary disorders with an allergic basis.

Pharmacology

Omalizumab is a recombinant humanized antibody developed for therapy of allergic diseases that has significant efficacy in severe atopic asthmatics.[106] By specifically binding with high affinity to free IgE, but not to other immunoglobulins, omalizumab does not activate mast cells or basophils. Clinical efficacy depends upon near total elimination of circulating IgE; therefore, the role of omalizumab is limited to those asthmatics with elevated serum IgE levels. Subcutaneous administration of omalizumab produces rapid binding of circulating IgE, with serum levels slowly rebounding over the subsequent 4 to 6 weeks.

Randomized, double-blind, placebo-controlled studies of omalizumab have been completed in patients more than 12 years of age who have moderate or severe atopic asthma refractory to high-dose inhaled corticosteroids alone. Studies have also been conducted in patients with severe asthma ages 6 to 12 years and greater than 12 years who were also receiving inhaled, long-acting β-agonists and oral leukotriene antagonists.[107] Use of omalizumab reproducibly decreased the frequency of asthmatic flares, reduced inhaled and oral steroid dosage, and improved quality of life scores. Although not approved for use in pregnant women, long-term observational registry data provide no evidence of an increased risk of major congenital anomalies among pregnant women exposed to omalizumab when compared with a disease-matched unexposed cohort.[108]

Ligelizumab, a fully humanized monoclonal antibody that binds human IgE with higher affinity than omalizumab, is currently under investigation in clinical trials. In patients with mild allergic asthma, ligelizumab had greater efficacy than omalizumab in blunting bronchoprovocation responses.[109]

Clinical Use

Omalizumab therapy is indicated for moderate or severe asthmatics who have serum IgE levels exceeding 30 IU/mL (75 ng/mL) and an allergic basis for their asthma, as demonstrated by positive skin testing or radioallergosorbent tests (RASTs) to common antigens. Although several early trials demonstrated efficacy of omalizumab when added to monotherapy with inhaled corticosteroids alone, current guidelines recommend addition of omalizumab to combined therapy using both inhaled corticosteroids and inhaled, long-acting β-agonists.[16] As a chronic therapy, omalizumab treatment should not be initiated in the setting of an acute asthma flare. Subcutaneous administration of omalizumab every 2 to 4 weeks is required to maintain reductions in circulating IgE, with the required dose and frequency dependent upon body weight and initial serum IgE level. Up to three separate subcutaneous injections, each not exceeding 150 mg at a single site, may be required at each administration. When pretreatment serum IgE levels exceed 300 IU/mL, omalizumab should not be administered to patients whose body weight exceeds

90 kg; with high pretreatment serum IgE levels, for example, levels approaching 700 IU/mL, omalizumab should not be administered, even to individuals of normal weight. Subsequent serum IgE measurements are unnecessary, as levels plummet to negligible levels and slowly rebound after each administration of the drug.

The total duration of necessary therapy is unclear, although a review every 6 to 12 months is commonly employed to assess whether improved asthma control has been achieved (as indicated by reduced inhaled and oral steroid usage, fewer emergency medical encounters and hospitalizations, and decreased overall medical costs).[110] In addition, withdrawal of omalizumab can be associated with increased asthma exacerbations.[111] Because of high acquisition costs, the cost-effectiveness of omalizumab remains controversial.[112]

Safety

Minor local skin reactions at the injection sites occur in almost one-half of patients. A diffuse urticarial rash has been reported, but it is extremely uncommon. Severe hypersensitivity reactions, including anaphylaxis, are rarely observed (rate of 1–2 per 1000 patients receiving omalizumab).[113] Therefore, close observation, including frequent assessment of vital signs, is recommended for at least 2 h following initial drug administration; similar monitoring is warranted for at least 1 h following each subsequent administration. Omalizumab should not be self-administered, although self-administration was allowed during the recent coronavirus pandemic.[114,115]

RECENT ANTI-INTERLEUKIN AGENTS

Recognition of the role of interleukins in mediating inflammation has led to development of a variety of anti-interleukin agents.

■ Mepolizumab

Mepolizumab is a humanized, mouse monoclonal antibody directed against human IL-5. Intermittent intravenous of the agent reduces peripheral blood and sputum eosinophil counts.

Pharmacology

Eosinophils play a role in the development of diverse inflammatory responses and have long been thought to play a pathogenetic role in the inflammation of asthma. Eosinophils migrate from the bloodstream to sites of inflammation, including the tracheobronchial epithelium, where they participate in antigen presentation and release of other inflammatory cytokines, as well as disgorge their own cytotoxic granules. Although IL-3 and GM-CSF have important stimulatory effects upon eosinophils, IL-5 is the most specific stimulant of eosinophil growth and activity, mediated through the IL-5 receptor complex expressed on the surface of eosinophils.

Clinical Use

Monoclonal antibodies directed against IL-5 failed to demonstrate efficacy in initial clinical trials performed in patients with asthma, in contrast to clear effectiveness in patients with hypereosinophilic syndromes. Subsequently, in a large, international, multicenter, double-blind, placebo-controlled trial, patients with eosinophilic asthma were randomized to receive monthly intravenous mepolizumab (75 mg, 250 mg, or 750 mg) infusions or placebo for 1 year.[116] In a dose-dependent manner, mepolizumab reduced clinically significant asthma exacerbations, along with both blood and sputum eosinophil counts. The efficacious effects of mepolizumab, including reduced hospitalizations, seem to be limited to patients with severe, eosinophilic asthma accompanied by peripheral eosinophilia, who often require concurrent oral and high-dose inhaled corticosteroids.[117–119]

Mepolizumab is also effective in eosinophilic granulomatosis with polyangiitis, and under investigation for patients with an eosinophilic phenotype of COPD.

Safety

Mepolizumab appears to be well tolerated, with relatively few significant adverse reactions equally reported in both treatment and placebo groups. The most frequently reported adverse events are headache and symptoms of respiratory infections; no serious life-threatening or anaphylactic reactions related to mepolizumab have been reported.[120]

■ Dupilumab

IL-4 and IL-13 have been implicated in the pathogenesis of asthma and atopic diseases, with inflammatory activity from these cytokines present in almost half of the patients with asthma. IL-4 and IL-13 signal inflammatory cells through two distinct receptors, although both receptors contain an α subunit of the IL-4 receptor. Dupilumab, a human monoclonal antibody to the IL-4 receptor α subunit, inhibits both IL-4 and IL-13 signaling.

A double-blind, placebo-controlled trial assessed the efficacy and safety of dupilumab in adults with persistent, moderate-to-severe asthma and elevated blood or sputum eosinophil levels, despite appropriate use of LABAs and inhaled corticosteroids.[121] After initiating administration of dupilumab or placebo subcutaneously once weekly, both LABAs and inhaled corticosteroids were withdrawn. Significant improvements were observed in spirometric values and asthma control, and withdrawal of LABAs and inhaled corticosteroids precipitated fewer asthma exacerbations in patients receiving dupilumab. However, only a minority of asthmatics have blood or sputum eosinophilia, and whether dupilumab will add incremental value to standard therapy with LABAs and inhaled corticosteroids remains to be seen.

■ Daclizumab

Airway inflammation in asthma includes activation of T cells and, consequently, increased levels of IL-2 and soluble IL-2 receptor (IL2R), all of which contribute to airway inflammation. Daclizumab is a humanized, monoclonal murine antibody that specifically binds to the α subunit of the high-affinity IL2R, thereby inhibiting IL-2 binding and subsequent activity.[122] Initially, the agent received FDA approval for induction immunosuppression and rejection prophylaxis of patients receiving renal transplantation. Daclizumab has limited availability due to market competition from basiliximab, used for immunosuppression in the setting of renal transplantation.

In a double-blind, placebo-controlled study, 116 patients with moderate or severe persistent asthma on stable doses of inhaled triamcinolone were randomized to receive intravenous infusions of daclizumab or placebo every 2 weeks for 5 months. Daclizumab improved FEV_1, reduced asthma symptoms, and delayed exacerbations.[122] However, an excess number of serious adverse events occurred in those treated with daclizumab, including an episode of severe anaphylaxis. In contrast, prior to withdrawal from the marketplace, daclizumab appeared to be generally well tolerated, in both renal transplant patients and those with inflammatory diseases receiving the drug off-label.

PHOSPHODIESTERASE 4 INHIBITORS

A new area of interest has evolved in the development of phosphodiesterase 4 (PDE4) inhibitors in the management of airways diseases.

■ Pharmacology

Roflumilast is the first-in-class isozyme-selective PDE4 inhibitor to be marketed in the United States. Although nonselective PDE inhibitors (i.e., theophylline, aminophylline) have been used for decades to treat obstructive lung diseases, roflumilast represents a markedly different type of medication.

PDEs hydrolyze cAMP and cGMP to inactive 5′ monophosphates; inhibition of PDE increases intracellular concentrations and, therefore, the activity of these secondary messengers.[123] Intracellular cAMP regulates cytokine and chemokine release from inflammatory cells and cell trafficking.

There are 11 known isoenzymes in the PDE superfamily (PDE 1–11).[124] The PDE 4 isoenzyme is expressed in lung inflammatory (neutrophils, monocytes, macrophages, and CD4+ and CD8+ T lymphocytes) and structural (sensory nerves, smooth muscle cells, fibroblasts, endothelial cells, epithelial cells) cells; PDE 4 inhibition reduces lung inflammation and remodeling.[123,124]

Roflumilast is well absorbed following oral administration and has an absolute bioavailability of about 80%.[125] The drug is rapidly metabolized by cytochrome P450 (CYP450) isoenzymes to roflumilast N-oxide, the major active metabolite that accounts for approximately 90% of the PDE 4 inhibitory activity. Roflumilast N-oxide is metabolized by CYP450 isoenzymes to inactive metabolites. Both roflumilast and its metabolites are excreted in the urine. The long plasma half-lives of roflumilast (approximately 20 h) and roflumilast N-oxide (30 h) allow the medication to be administered once daily.

Drug Delivery

Roflumilast is marketed as a 500-μg tablet. Food does not affect absorption; patients may take it with or without food, although given the pharmacokinetic and pharmacodynamics profile, patients should take the dose at the same time every day.

Clinical Use

Roflumilast is FDA approved for the treatment of patients with severe COPD associated with chronic bronchitis and a history of exacerbations. The current GOLD guidelines recommend roflumilast as add-on therapy for two clinical situations: (1) patients experiencing exacerbations despite dual therapy with LABA/LAMA if blood eosinophils are less than 100 cells/μL, and (2) patients experiencing exacerbations with chronic bronchitis, FEV_1 less than 50%, and at least one hospitalization for an exacerbation while on triple therapy with LABA/LAMA/ICS.[17] A systematic review of 28 randomized controlled trials concluded that patients with moderate to very severe COPD treated with roflumilast had small, but clinically insignificant, improvements in FEV_1, improved quality of life, and reduced likelihood of COPD exacerbations with no effect on mortality.[126]

Safety

Concerns regarding the relative risks and small benefits of roflumilast resulted in the FDA's Pulmonary-Allergy Drugs Advisor Committee's vote against approval of the drug.[127] Although generally well tolerated, roflumilast has PDE 4 inhibitor class-specific gastrointestinal (diarrhea, nausea, decreased appetite) and neuropsychiatric (insomnia, anxiety, depression, mood changes, suicidality) adverse effects.[126] Unexplained weight loss, typically <3% of baseline body weight, has been reported with roflumilast. Patients should be advised of the possibility of these adverse effects and monitored closely during treatment with roflumilast. Roflumilast is contraindicated in Child–Pugh B or C liver impairment.

Many drugs interact with roflumilast.[128] Strong inducers of CYP450 (e.g., carbamazepine, phenobarbital, phenytoin, rifampin) reduce the effect of roflumilast and should be avoided. CYP3A4 or dual CYP3A4/CYP1A2 inhibitors (e.g., cimetidine, enoxacin, erythromycin, fluvoxamine, ketoconazole) increase the effect of roflumilast and also should be avoided.

Clinical experience with roflumilast in patients with immunologic disorders and serious infections is limited. Until more data are available, roflumilast should not be used in patients with severe immunologic disorders, severe acute infections, or latent infections (e.g., tuberculosis, herpes viral infections, viral hepatitis).[128] Concurrent use of roflumilast with immunosuppressants, including long-term systemic corticosteroids, is not recommended.[128]

MUCOACTIVE AGENTS

Chronic sputum production or inspissated airway secretions trouble most patients with obstructive lung disease. Mucus, which consists of a tangled network of mucin glycoproteins, oligosaccharide side chains, water, and electrolytes, is produced by goblet cells and submucosal glands and is cleared by ciliary action; sputum (expectorated mucus) is cleared by cough. Inflammatory-derived substances (neutrophil-derived DNA, filamentous actin, cells and cellular debris, and bacteria) alter the physical characteristics of mucus.

Mucoactive drugs (expectorants, mucolytics, mucoregulators, mucokinetics) modify mucus viscoelastic properties and enhance mucus clearance.[129] Expectorants increase mucus secretion or increase airway water to facilitate mucus expulsion from the airways. Mucolytics directly decrease mucus viscosity. Mucoregulator drugs, such as the anticholinergics and glucocorticoids, decrease mucus secretion and improve mucociliary clearance, respectively. Mucokinetic drugs (e.g., β_2-adrenergic agonists) enhance ciliary activity.

Expectorants

FDA-approved expectorants include guaifenesin, available in multiple nonprescription and prescription products, and potassium iodide. The mechanism of action of guaifenesin (glyceryl guaiacolate) is unclear. Guaifenesin may suppress mucin production, stimulate gastric vagal receptors triggering cholinergic parasympathetic reflexes, alter mucus adhesiveness and surface tension, and increase mucus hydration.[130] Guaifenesin is not recommended in the current American College of Chest Physicians evidence-based cough guidelines.[131,132] Despite a lack of proven efficacy, guaifenesin, with few adverse effects or drug interactions, is a common component in numerous nonprescription cough medications.

Aerosolized hypertonic saline is used in the management of cystic fibrosis and non–cystic fibrosis bronchiectasis and to induce sputum for diagnostic and research purposes. The mechanism of action is unclear, but aerosolized hypertonic saline may increase airway surface liquid layer volume and decrease bronchial epithelial cell volume.[133] Although evidence is limited, regular use of hypertonic saline by adolescents greater than 12 years of age and adults with cystic fibrosis may improve lung function, reduce exacerbations, and improve quality of life.[134] Adverse reactions to aerosolized hypertonic saline include bronchospasm, cough, and breathlessness.[135] The mechanism of action of potassium iodide as an expectorant is not known. Efficacy data are limited.[131] Potassium iodide may cause significant adverse effects (hypersensitivity, dermatitis, hypothyroidism, chronic iodide poisoning) and must be used with caution in patients with Addison disease, cardiac disease, and renal impairment. Potassium iodide is contraindicated during pregnancy.

Mucolytics

Drugs that directly reduce mucus viscosity are classified as classic (e.g., N-acetylcysteine [NAC]) or peptide (e.g., dornase alfa) mucolytics. When administered as an aerosol, the NAC free thiol sulfhydryl group hydrolyzes the disulfide bonds that link mucin strands, resulting in less viscid mucus.[136] Evidence for efficacy of aerosolized or oral thiols in the treatment of cystic fibrosis is limited.[137] Aerosolized NAC is acidic (pH 2.2); pretreatment with inhaled bronchodilators is necessary to reduce NAC-associated cough and bronchospasm.[137]

Dornase alfa, purified recombinant human deoxyribonuclease, depolymerizes DNA and F-actin polymers, reducing sputum adhesiveness. FDA approved for the management of cystic fibrosis, dornase alfa improves lung function and reduces exacerbations.[138] Dornase alfa is administered by nebulizer once daily. Limited data suggest that timing of administration (time of day or before or after airway clearance) has no impact on clinical outcomes.[139]

ANTITUSSIVES

Antitussives (cough suppressants) are used for the symptomatic treatment of cough associated with a variety of acute and chronic medical conditions. The number of FDA-approved antitussives is limited; no new antitussives have been approved for decades. Data regarding efficacy and comparative efficacy in specific medical conditions are limited.

■ Pharmacology

Cough is a complex coordinated neuromuscular response to mechanical and sensory stimuli in the larynx, trachea, and bronchi.[140] The medullary brainstem cough center controls involuntary cough in response to mechanical and chemical stimulation and is interconnected with suprapontine voluntary control of cough.[141]

Antitussives are classified as centrally acting or peripherally acting, depending on the site of action. Centrally acting opioid (codeine, hydrocodone, and morphine) and nonopioid (dextromethorphan, diphenhydramine, and chlophedianol) antitussives suppress cough by acting on the medullary cough center. Benzonatate, a procaine derivative, inhibits peripheral pulmonary stretch receptors. Levodropropizine and moguisteine (neither available in the United States) may modulate peripheral sensory neuropeptide levels throughout the respiratory tract.[142,143] Guaifenesin may have antitussive effects in acute viral cough, although the evidence is limited and contradictory.[144]

Drug Delivery

Antitussive medications are available in a variety of product-specific formulations, including solutions (liquids, extended-release liquids, syrups, elixirs, and gels) and solid dosage forms (lozenges, capsules, tablets, chewable tablets, and oral disintegrating strips). Alcohol-, sugar-, dye-, and gluten-free and single-ingredient antitussive products are available, although most products contain multiple additional active ingredients (e.g., expectorants, decongestants, analgesics, antihistamines). The majority of states allow codeine-containing antitussives to be sold as nonprescription medications if the products contain one or more non-codeine active ingredients and a maximum of 200 mg of codeine per 100 mL.[145]

Clinical Use

The ACCP Evidence-Based Clinical Practice Guidelines recommend codeine or dextromethorphan for short-term symptomatic relief of cough associated with acute and chronic bronchitis and postinfectious cough, and centrally acting antitussives, such as dihydrocodeine and hydrocodone, for chronic cough associated with lung tumors.[131] Evidence for the efficacy of antitussives in the management of other medical conditions, including cough due to viral upper respiratory tract infections, is lacking.[146–149]

Safety

Questions regarding the safety of opioid-containing cough medications prompted the FDA to limit the use of prescription codeine and hydrocodone cough medications to adults 18 years of age and older.[150] Although the FDA has not taken action on opioid or nonopioid nonprescription cough and cold medications, manufacturers voluntarily restricted labeling to state "do not use" in children under 4 years of age.[151]

Common side effects associated with opioid antitussives include sedation, constipation, nausea, and vomiting. At antitussive dosages, dextromethorphan has a wide margin of safety; side effects similar to codeine occur infrequently. Side effects of chlophedianol include excitation, hyperirritability, and hallucinations. Benzonatate may cause drowsiness or dizziness; capsules should be swallowed whole to avoid the local anesthetic effect of the liquid capsule contents.

Codeine and dextromethorphan are abused for the CNS effects associated with high doses. Robotripping, intentional abuse of dextromethorphan-containing cough medications for the dissociative hallucinogenic effects, is well known, especially among adolescents. At higher than approved doses, dextromethorphan is associated with dose-dependent symptoms ranging from mild motor and cognitive impairment at low doses (1.5–2.5 mg/kg) to complete psychophysical dissociation at high doses (>15 mg/kg).[152] In 2010, an FDA advisory panel considered, but voted against, recommending that dextromethorphan be scheduled in the Controlled Substance Act.[153]

PHYSIOLOGIC REPLACEMENTS

Replacement therapy comprises a novel class of agents to replace deficient, or augment existing, endogenous substances. To date, replacement therapy has been employed only in adults with α_1-antitrypsin deficiency or neonates with respiratory distress syndrome. However, clinical studies of replacement therapy are ongoing in patients with a wide spectrum of obstructive and other lung diseases.

■ α_1-Antitrypsin

α_1-Antitrypsin is a glycoprotein synthesized and secreted largely by hepatocytes. A protease inhibitor, α_1-antitrypsin blocks the actions of neutrophil-derived elastase in the lung. Inherited deficiency of α_1-antitrypsin promotes development of emphysema in adulthood; tobacco smoking rapidly accelerates the clinical presentation and severity of the emphysema. Since 1987, α_1-antitrypsin replacement therapy has been available for intravenous administration as a purified product derived from pooled human plasma.

Clinical Use

Weekly or monthly intravenous infusion of α_1-antitrypsin to deficient patients increases α_1-antitrypsin levels in serum and bronchoalveolar lavage specimens and restores antielastase activity in serum and alveolar lining fluid. Numerous case reports and small series dispute whether α_1-antitrypsin replacement reduces the accelerated rate of decline in pulmonary function, CT-measured lung density, or mortality associated with α_1-antitrypsin deficiency.[154–156] The absence of clear efficacy data and high cost have prevented governmental approval for administration of replacement therapy in many countries. However, the withdrawal of governmental financing of replacement therapy led to an extremely rapid and prevalent increase in exacerbations, leading to reinstitution of financing.[157]

Currently, weekly α_1-antitrypsin replacement infusions of 60 mg/kg are recommended for patients with α_1-antitrypsin deficiency who are older than 18 years of age, maintain complete tobacco abstinence, and have both abnormal pulmonary function tests and a serum α_1-antitrypsin level less than 11 mM.[17,158,159] Replacement therapy for α_1-antitrypsin deficient patients is not recommended following lung transplantation.

Side Effects

α_1-Antitrypsin replacement therapy is remarkably nontoxic, and current preparations have few side effects, other than mild fever, headache, dyspnea, or dizziness. Repeated administration of α_1-antitrypsin does not shorten the serum half-life, suggesting that α_1-antitrypsin antibodies do not develop, even in patients with complete deficiency.

Pulmonary Surfactant

The administration of pulmonary surfactant to premature infants with, or at risk for, respiratory distress syndrome remains in practice as an alternative or supplement to nasal continuous positive airway pressure.[160] Surfactant administration decreases mortality from respiratory distress syndrome by 30% to 40% and reduces morbidity due to pneumothoraces, interstitial emphysema, bronchopulmonary dysplasia, and intraventricular hemorrhage. Traditionally administered intratracheally via intubation, newer methods including nebulized administration or a thin, endotracheal catheter transiently placed during nasal continuous positive-pressure ventilation are in clinical trials.[161,162] In addition, surfactant administration may have a role in neonates with meconium aspiration syndrome and respiratory failure, reducing the need for mechanical ventilation or extracorporeal membrane oxygenation, and hospital length of stay but not mortality.[163]

Endogenous pulmonary surfactant is an emulsion of phospholipids, cholesterol, and apoproteins that reduces surface tension within alveoli. Natural surfactant is commercially available and is prepared from bovine or porcine lung tissue or lavages. Synthetic surfactant was initially available from a number of commercial sources, but it was withdrawn from the market due to superiority of natural surfactant. However, newer-generation synthetic surfactants, enriched in peptide analogues of the human surfactant proteins B and C, are currently in clinical trials.[164]

Pulmonary surfactants reduce oxygen toxicity by scavenging free radicals, and the surfactants may be cytoprotective for alveolar cell surfaces. Pulmonary surfactants suppress mediator release by inflammatory cells and may deactivate inflammatory mediators upon release. In vitro studies indicate that surfactant suppresses lymphocyte mitogenic responses, leading to a decrease in inflammatory cell influx. Pulmonary surfactant has both antibacterial and antiviral properties that are mediated by an increase in alveolar macrophage phagocytosis. Surfactant may promote airway clearance by changing the physical properties of mucus, as well as by increasing ciliary beat frequency. Finally, pulmonary surfactant may directly relax airway smooth muscle. This spectrum of putative biologic activities may directly interrupt the pathogenesis of airway inflammation, chronic infection, and bronchoconstriction seen in most obstructive lung diseases.

In adults with respiratory failure, multiple placebo-controlled trials showed that administration of synthetic surfactant yielded no demonstrable physiologic benefit and no significant decrease in mortality rate. Similarly, the most recent trial using bovine surfactant yielded no significant improvements in oxygenation, length of stay, or survival at the first interim analysis and was discontinued.[165]

RESPIRATORY STIMULANTS

Respiratory stimulants are a group of pharmacologically unrelated agents used to treat diverse pathophysiologic conditions, including COPD, postanesthesia respiratory depression, apnea of prematurity, acute mountain sickness, and obstructive or central sleep apnea.

Acetazolamide

Acetazolamide is a noncompetitive inhibitor of carbonic anhydrase that induces a weak diuresis and mild metabolic acidosis. FDA-approved indications include acute mountain sickness (prophylaxis and adjunctive treatment), edema, epilepsy, and glaucoma.

Acetazolamide may have both indirect and direct respiratory stimulant properties.[166] The increased hydrogen concentration indirectly stimulates respiration via peripheral and medullary chemoreceptor stimulation. Acetazolamide may also directly stimulate respiration by increasing cerebral blood flow through mechanisms unrelated to the metabolic acidosis.[167] In one small clinical trial, the combination of acetazolamide and auto-continuous positive-airway pressure improved nocturnal oxygen saturation and reduced the apnea/hypopnea index in patients with obstructive sleep apnea at altitude.[168] In a large, randomized, double-blind, multicenter trial in patients with COPD receiving invasive mechanical ventilation, acetazolamide did produce a statistically significant reduction in the duration of invasive mechanical ventilation.[169]

Side effects include drowsiness, numbness or tingling of the face and extremities, tinnitus, hypokalemia, and gastrointestinal upset. Long-term safety and efficacy data for use as a respiratory stimulant are unavailable.

Almitrine

Almitrine bismesylate increases alveolar ventilation and improves ventilation–perfusion mismatching by stimulating peripheral aortic and carotid chemoreceptors and enhancing hypoxic pulmonary vasoconstriction.[170,171] Small clinical trials of sequential treatment in patients with moderate or severe COPD and hypoxemia demonstrate a small, dose-dependent improvement in oxygenation.[172,173] Investigational in the United States, but approved as a respiratory stimulant in Europe, side effects, including peripheral neuropathy[174] and weight loss, limit the clinical usefulness of the drug.

Doxapram

Doxapram is a short-acting, parenterally administered respiratory stimulant. FDA-approved indications include respiratory depression following anesthesia, acute hypercapnia secondary to COPD, and drug-induced respiratory depression; off-label uses include treatment for apnea in premature infants, weaning from mechanical ventilation, and obstructive sleep apnea.[175,176] Doxapram exhibits dose-dependent peripheral chemoreceptor agonist and central respiratory stimulant properties.[175] Limited case reports and small studies describe use of doxapram as a respiratory stimulant in COPD complicated by acute respiratory failure.[177] Benzyl alcohol–containing solutions may cause significant adverse effects in infants, including metabolic acidosis, hypotension, and the “gasping syndrome.”[175] Doxapram-associated side effects include flushing, sweating, elevated blood pressure, and muscle spasticity.

Medroxyprogesterone

Medroxyprogesterone acetate is a synthetic progesterone hormone with central and peripheral respiratory stimulant properties.[178,179] Although the mechanism of action is unclear, medroxyprogesterone increases minute ventilation and produces hypocapnia in normal subjects. However, it does not improve breathing disturbances during sleep in patients with obstructive sleep apnea.[180] Limited data show that medroxyprogesterone improves oxygenation and hypercapnia in patients with hypercapnic obstructive lung disease.[168,181] Medroxyprogesterone side effects include thromboembolic disorders, elevated liver function tests, visual disturbances, breast tenderness, reduced bone mineral density, edema, and gastrointestinal upset.

Methylxanthines

Caffeine, theophylline, and aminophylline are structurally related methylxanthines with bronchodilatory and respiratory stimulatory properties (see above). Caffeine is FDA approved for the treatment of apnea of prematurity and respiratory depression in adults. The mechanism of respiratory stimulation is not known, but it may include enhanced medullary respiratory center chemoreceptor responsiveness to carbon dioxide, improved diaphragmatic contractility, and competitive adenosine inhibition.[182,183] Caffeine is the most effective methylxanthine for the treatment of apnea of prematurity, and it may protect against acute kidney injury.[184,185] Common side effects include tachycardia, jitteriness, and increased gastric aspiration.[187] Caffeine inhibits adenosine receptors, creating a theoretical risk of cerebral damage and impaired neuronal development.[187] No neurodevelopmental disability was reported 18 to 21 months post-treatment in very low-birth-weight infants.[188] When compared with placebo-treated controls, 11 years following caffeine therapy for the apnea of prematurity, children have improved expiratory airflows, neurobehavioral outcomes, and motor impairments without adverse changes to self-reported health-related quality of life.[189–192]

CHAPTER 145

Intubation and Upper Airway Management

Joshua H. Atkins
Christopher H. Rassekh

INTRODUCTION

Management of the upper airway, in both acute and elective settings, requires significant expertise, proper equipment, and organizational structure. Airway management is generally an interprofessional and interdisciplinary team effort that is enhanced by coordination and planning. Complications from a difficult intubation or problems from tracheostomy create may lead to considerable morbidity and mortality. Closed-claims analysis of medicolegal cases in anesthesiology reveals that litigation for patient harm related to airway management is generally associated with severe morbidity related to intubation and tracheostomy.[1,2] Multidisciplinary management of the airway, operator preparedness, and team communication are critical to preventing such complications.[3]

This chapter reviews anatomic considerations, clinical airway assessment in both the emergent and elective settings, and multidisciplinary considerations in airway management. The narrative specifically addresses refinements in equipment and techniques that allow for safer patient care. In addition, as systems-based initiatives and practice-based learning are critical, we highlight some of the concepts that allow members of the airway team to improve their fund of knowledge and technical skills related to airway management.

UPPER AIRWAY ANATOMY AND CLINICAL RELEVANCE

The approach to any clinical problem begins with a solid understanding of both normal anatomy and alterations associated with disease-specific pathophysiology. Knowledge of the types of anatomic variations and specific pathologic entities that can alter the anatomy are fundamental to safe and effective airway management.

The "upper" airway is defined as the portion of the head and neck where there is airflow. Thus, the nasal cavity, oral cavity, pharynx, larynx, and upper trachea constitute the upper airway. Each of these anatomic sites has several subsites. The nasal cavity is divided into left and right sides by the nasal septum and includes the superior, middle, and inferior turbinates. The choana is the boundary between the nasal cavity and the nasopharynx. The oral cavity includes the teeth, mandible, and oral tongue; the oropharynx includes the base of tongue, tonsillar structures, posterior oropharynx, and soft palate. The area at the junction of the oropharynx and the nasopharynx is particularly important. As there is minimal cartilaginous support in this area, collapse of the pharyngeal wall is common with induction of anesthesia and may impair mask ventilation.

The larynx (Fig. 145-1) consists of supraglottic structures (the epiglottis, false vocal cords, and aryepiglottic folds) and the glottis (the true vocal cords). Below the glottis is the subglottis, which transitions to the trachea below the cricoid cartilage. The vallecula is considered part of the pharynx and constitutes a depression between the lingual surface of the epiglottis and the root of the base of the tongue. It is an important landmark for intubation, since Macintosh-style laryngoscope blades are designed to fit into the area, to lift the larynx, and to expose the glottis region. The epiglottis can also be lifted on the laryngeal surface, as is typically done using straight-blade and tubular (surgical) laryngoscopes. The hypopharynx is the area of the pharynx inferior to the epiglottis; it includes the pyriform sinuses (with anterior, medial, and lateral walls) bilaterally, and the posterior hypopharynx (which is the continuation of the oropharyngeal posterior wall to the entrance of the cervical esophagus and the postcricoid area). The length of the cervical trachea and cervical esophagus are variable, depending on the patient's neck length and body habitus; the distance between the bottom of the cricoid and the sternal notch defines these lengths. These dimensions are important because patients who have longer cervical tracheas provide easy access to the cricothyroid membrane and trachea, making both emergent and elective surgical airway

1) True vocal cord
2) False vocal cord
3) Laryngeal surface of epiglottis (lingual surface out of view)
4) Left arytenoid
5) Right aryepiglottic fold
6) Left pharyngoepiglottic Fold
7) Left vallecula (oropharynx)
8) Base of tongue (oropharynx)
9) Subglottic airway
10) Right pyriform sinus (hypopharynx)
11) Posterior hypopharyngeal wall
12) Interarytenoid region (larynx)
13) Postcricoid area (hypopharynx)

Note: Esophageal inlet is between #11 and #13.

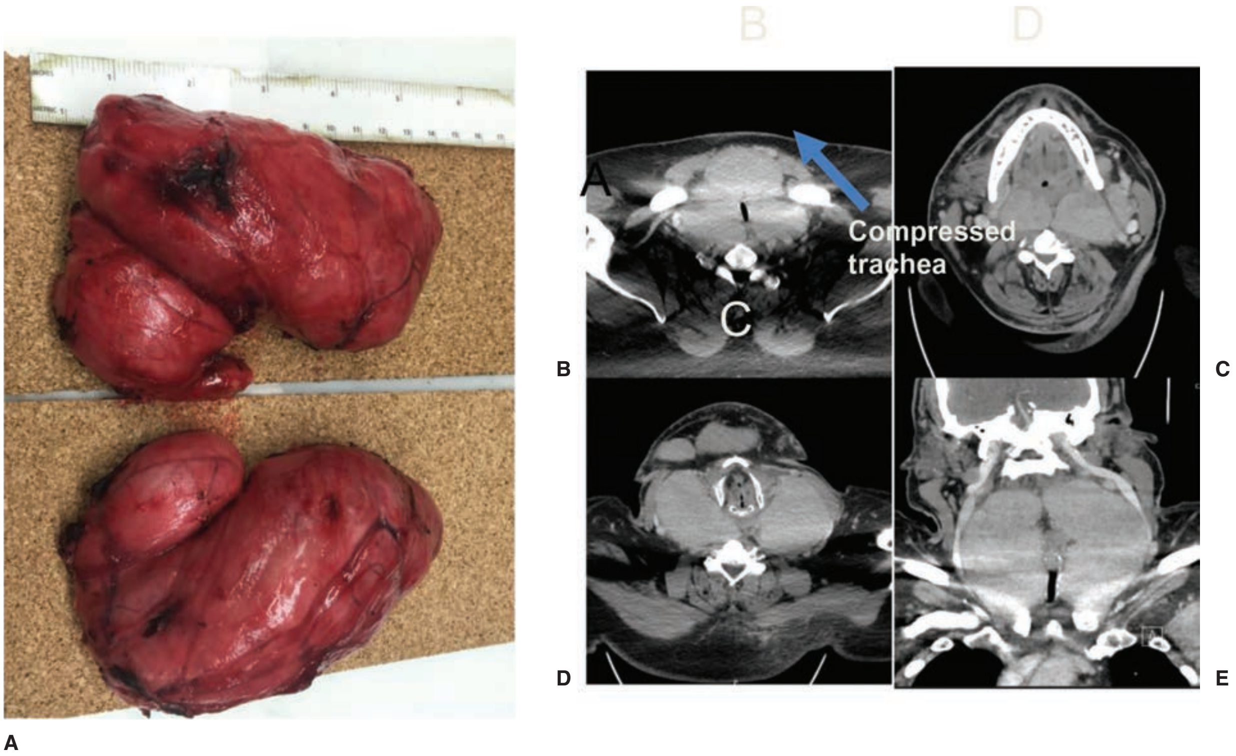

Figure 145-2 **A.** Gross thyroidectomy specimen from patient with sclerosing thyroiditis. Femoral wires were placed prior to sedation due to concerns about inability to ventilate or intubate. However, the patient was able to be ventilated and intubated and was extubated after the goiter was removed. **B.** Axial CT scan at level of trachea showing marked tracheal compression. **C.** Axial CT scan at level of larynx. **D.** Axial CT scan at level of oropharynx showing retropharyngeal extension. **E.** Coronal CT scan. *(Reproduced with permission from the personal collection of Christopher H. Rassekh.)*

access much more straightforward. Patients in whom the cricoid is not easily palpated, due to a short distance to the sternal notch, obesity, or limited neck mobility, should be identified as posing difficult surgical access.

The thyroid gland isthmus generally lies over the trachea, near the level of the cricoid cartilage. Since the thyroid is a very vascular organ, the preferred emergency surgical airway is usually a cricothyroidotomy, rather than a tracheostomy. However, if the clinical issue necessitating emergency airway access is subglottic, tracheostomy has to be considered, since a cricothyroidotomy may not bypass a proximal obstruction. If the thyroid is enlarged due to a massive goiter or malignancy overlying the airway, establishing an emergency surgical airway may be very difficult (Fig. 145-2).

Transnasal intubation is a good alternative for patients with limited mouth opening, prior head and neck irradiation, or oropharyngeal pathology. Important to note is that the anatomy of the nasal cavity may be altered by prior nasal surgery, a deviated septum, pathology of the lateral nasal wall, or hypertrophic turbinates. These conditions should be noted if nasal intubation is considered. In addition, the mucosa of the nasopharynx is highly vascular, and the risk of bleeding during transit of an endotracheal tube through the nasopharynx may be significant. Flexible fiber-optic nasopharyngolaryngoscopy (NPL) by an experienced clinician should be considered prior to elective nasotracheal intubation for anatomic assessment. Nasal intubation may be done under local anesthesia with maintenance of spontaneous respiration for patients deemed difficult candidates for oral intubation. Risk factors for difficult oral intubation are explored later in this chapter.

There are important differences between the normal adult and pediatric airways. One major difference is the stiffness, shape, and relative thickness of the epiglottis. This is relevant for oral intubation; the thinner, and relatively stiffer, adult epiglottis, with its wider arc and ligamentous attachments, can be lifted by placing a curved laryngoscope blade into the vallecula. In contrast, the more "omega-shaped" epiglottis in children, which is also longer and not as stiff, often requires lifting with a straight blade or a surgical-style laryngoscope to enable visualization of the glottis. Additionally, in adults, the diameter of the airway is smallest at the level of the vocal cords, whereas the tightest dimension in infants is the subglottic airway at the level of the cricoid cartilage. Of course, the pediatric larynx is smaller, and the vocal cords are a smaller proportion of the glottic length. The adult larynx is adjacent to the fourth to sixth cervical vertebrae, whereas the infant larynx is between C2 and C3; in addition, the superior portion of the pediatric larynx is angulated anteriorly, causing the plane of the glottis to be less parallel to the horizontal plane. Finally, the thyroid cartilage becomes ossified as patients age. Rare congenital syndromes may include substantial alteration of normal airway anatomy. Examples include Treacher Collins, Pierre Robin, Klippel–Feil, Goldenhar, Beckwith–Wiedemann, and Crouzon Syndromes, as well as mucopolysaccharidoses.

Infections, tumors, anatomic deformities, trauma, congenital anomalies, and other causes of swelling, such as angioedema, may markedly distort normal anatomy; different parts of the nasal, oral, pharyngeal, laryngeal, and tracheal airways are affected. A careful history and physical examination, even in the emergent setting, are important. When two or more of the issues noted are present, having a backup plan available that includes additional airway expertise is critical.

AIRWAY ASSESSMENT

Airway assessment and risk stratification prior to interventions are mandatory in order to devise an airway strategy and plan for potential challenges with mask ventilation, intubation, or both. Assessment includes physical examination and review of prior airway management, flexible fiberoptic procedure notes, radiology studies, and laboratory testing to assess for abnormalities in coagulation, platelet count, and serum potassium level. A rigorous approach to airway assessment may alert the clinician to warning signs that warrant a specialized approach. For example, someone who has tracheal stenosis and is predicted to have challenges with mask ventilation, as well as laryngoscopy, and who also has a cricoid cartilage that is difficult to palpate, should be considered for urgent transfer to the operating room for airway management. In extreme situations, consideration of the management of "can't ventilate, can't intubate, can't do surgical airway" may rarely require consideration of extracorporeal membrane oxygenation (ECMO).[4]

No foolproof strategy exists for predicting a challenging or impossible intubation. Backup plans and equipment should be in place for all airway management, since most challenging airways are unanticipated.[5] Considered in isolation, no component of airway assessment is 100% sensitive or specific in ruling in or out a difficult intubation. The combination of results from different assessments may be helpful in predicting a potentially difficult intubation.

A structured approach to airway assessment should include determination of a Mallampati score, measurement of mento-hyoid or mento-thyroid distance, approximation of the extent of mouth opening (as approximated by number of finger breaths), evaluation of jaw subluxation and neck range of motion, and identification of the cricoid cartilage.

The Mallampati score (Fig. 145-3) is most referenced; scores of 3 and 4 indicate greater concern for a difficult intubation. The upper lip bite test (Fig. 145-4) is an evaluation that is relatively specific (96%). In one study, 60% of patients with a class 3 finding in the upper lip bite test had a difficult airway. The test has been used increasingly.[6]

Some integrated scoring systems, such as the Wilson score (which incorporates metrics including weight, neck and jaw mobility, retrognathia, and prominent incisors), have been investigated and have demonstrated only modest predictive utility.[7] Obesity, neck circumference, presence of a beard are associated with difficult mask ventilation.[8] These features are also found frequently in patients with obstructive sleep apnea—a diagnosis that, itself, should raise concerns about mask ventilation.

A thorough inspection of the dentition may reveal loose or otherwise fragile teeth that could be displaced into the airway during intubation. Angulation of the dentition and length of the incisors should be inspected, as they may make intubation more difficult. Overlapping or crowded lower incisors may suggest a smaller mandible and anteriorly displaced larynx. Maryland bridges, in which the bridge is fixed into place by bonding to adjacent dentition, may be particularly susceptible to pressure-related injury from contact with the laryngoscope. Neck range of motion also is an important element of airway assessment, as it relates to the ability to align the axes during laryngoscopy.

Perhaps the most informative source of information about the airway is a prior airway management note. If a systemic process

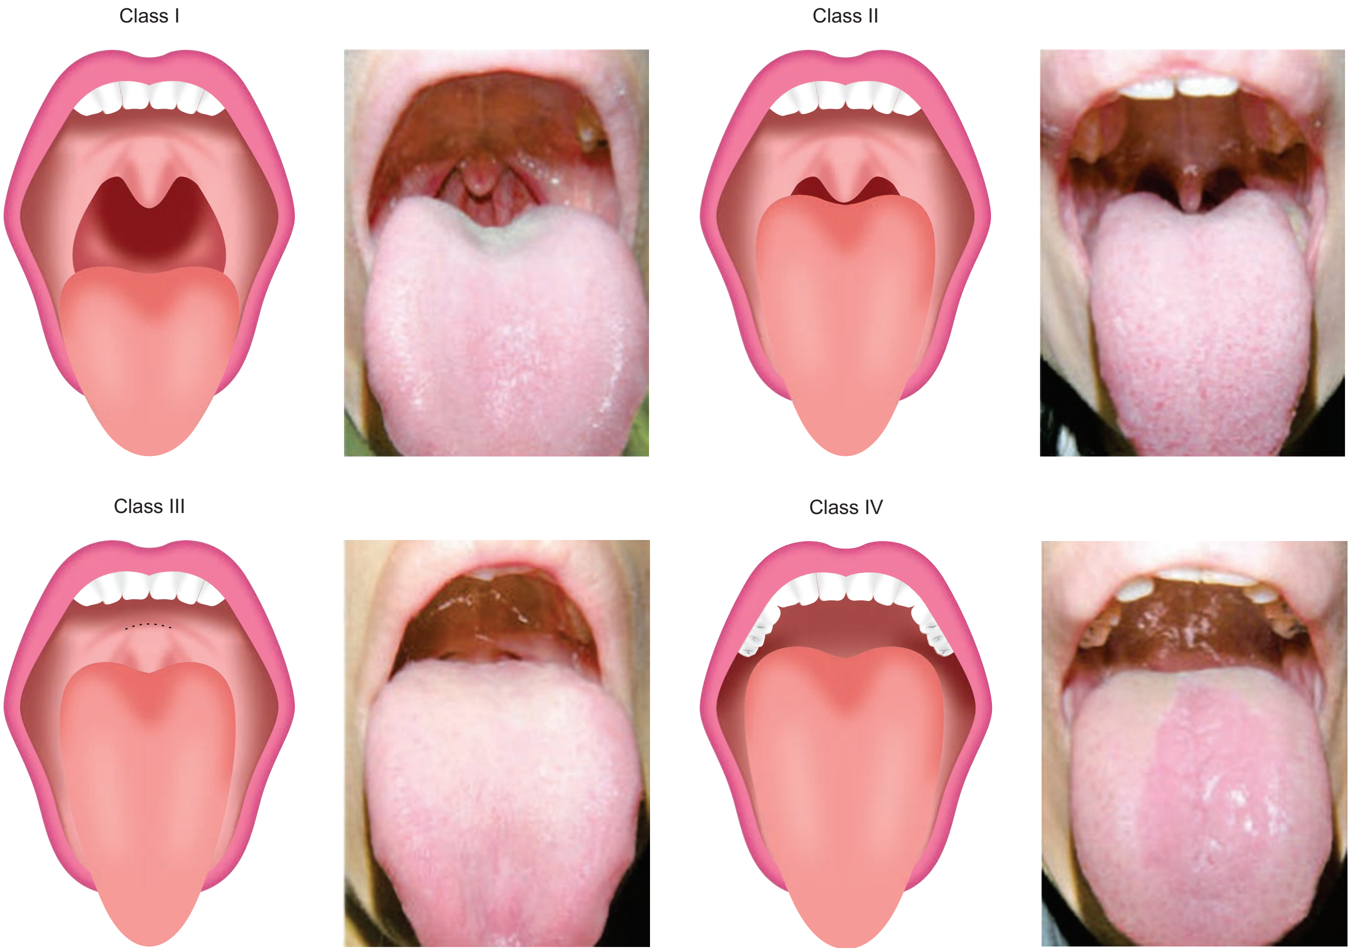

Figure 145-3 Mallampati scoring performed in the sitting position, with mouth maximally open, tongue maximally protruded, and, usually, without phonation. The Mallampati classification assesses the visibility of oropharyngeal structures when the mouth is maximally opened and the tongue protruded: class I, soft palate, fauces, uvula, pillars; class II, soft palate, fauces, uvula; class III, soft palate, base of uvula; and class IV, soft palate not visible. *(Modified with permission from Ouchi K, Hosokawa R, Yamanaka H, et al. Mallampati test with phonation, tongue protrusion and supine position is most correlated with Cormack-Lehane test. Odontology. 2020;108(4):617–625.)*

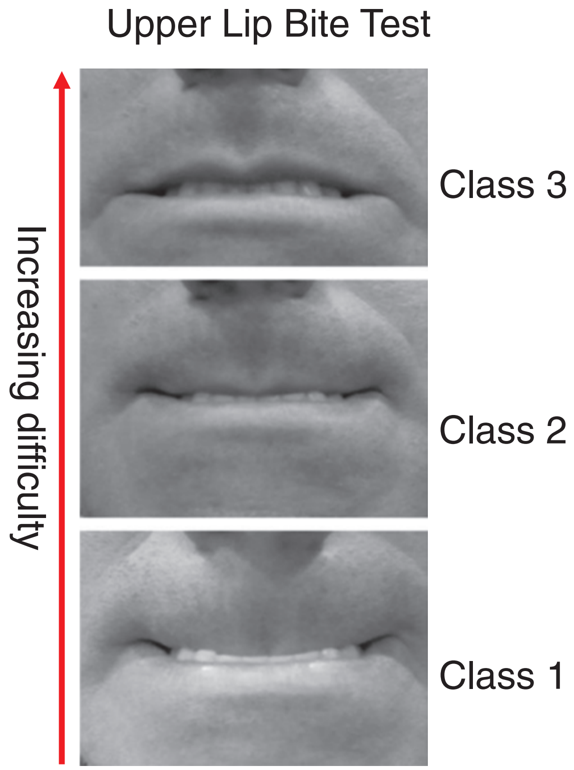

Figure 145-4 The upper-lip bite test is a commonly used adjunct to the Mallampati score. It assesses jaw mobility and has reasonable sensitivity in predicting difficult laryngoscopy. *(From Joffe AM, Deem S. Airway management. In: Tobin MJ, ed. Principles and Practice of Mechanical Ventilation. 3rd ed. New York, NY: McGraw-Hill; 2013. Reproduced with permission from Dr. Aaron M. Joffe.)*

(e.g., angioedema, SVC syndrome) or therapy (e.g., neck irradiation) has arisen since the last airway intervention, prior notes may not be applicable. Neck irradiation immobilizes tissues, such as the epiglottis and tongue, and may contribute to necrosis of the temporomandibular joint, resulting in limited mouth opening.

Also important to know is whether the patient has abnormalities in coagulation, including quantitative or qualitative platelet abnormalities, since contact of the relatively fragile oropharyngeal mucosa with the rigid laryngoscope may result in significant bleeding. This is particularly true when considering nasal intubation.

For cases involving known or suspected airway pathology (e.g., stenosis, tumor, or edema), it is important to consider a preintubation fiberoptic evaluation of the pharynx and larynx. If nasal intubation is planned, examination of the nasal cavity for any obstructive anatomy (e.g., deviated septum, or large turbinates or adenoids) or pathology (e.g., polyps, tumors) is also important. Occluding alternating sides of the nose may help predict nasal obstruction prior to placing a nasal airway. Nasal intubation may be used in the urgent setting when oral intubation is deemed to be difficult or hazardous (e.g., angioedema); it may also be helpful when addressing specific pathology of the oral cavity and oropharynx, where an oral tube may make access to pathology more difficult.

CLINICAL SETTING

The clinical setting is an important consideration with regard to upper airway management. Conditions in the operating room or procedural suite differ markedly from the general inpatient or intensive care (ICU) setting. Likewise, elective and emergent airway interventions are fundamentally different procedures. Most airway management on the general hospital floor or in the ICU is urgent or emergent and is performed on patients with significant respiratory compromise and physiologic frailty. Few parameters can be readily optimized, and physiologic reserve is minimal. These include issues related to volume status, oxygenation, cardiovascular function, and patient position, due to the limitations of the hospital bed and the unit's monitoring capabilities. In general, the equipment and airway expertise available on a general patient floor or in a remote location, such as radiology, will be limited, and support staff may have less working familiarity with less frequently used airway equipment. Overall, difficult intubating conditions are most likely to be encountered in the ICU or remote locations.[9] These factors all enhance the need for careful planning, acknowledgement of limitations, and robust systems for emergency backup. Fortunately, technologic advances in respiratory support and airway management equipment provide the clinician with a substantial armamentarium to aid in managing complex situations.

OXYGENATION, DENITROGENATION, AND RAPID SEQUENCE INDUCTION

The majority of intubations are performed with the patient asleep and following pharmacologically induced ablation of spontaneous ventilation; however, intubation with maintenance of spontaneous ventilation can and should be considered if difficult laryngoscopy is anticipated. Denitrogenation (colloquially referred to as "preoxygenation") of the lungs prior to intubation fills the functional residual capacity (FRC) of the lungs with oxygen and generally decreases the rate and extent of desaturation during intubation-associated apnea.[10] Denitrogenation is one of the most important steps in upper airway management and is challenging in critically ill patients with respiratory compromise and delirium.

The most common strategy for denitrogenation is use of a self-inflating bag-valve-mask (BVM) and 100% oxygen administered at a flow rate sufficient to wash out carbon dioxide and prevent rebreathing. An oxygen reservoir can be attached to the apparatus to increase the inspired Fi_{O_2}; a PEEP valve can be used if indicated. Imperative is maintenance of a good mask-to-face seal, which frequently requires two hands. An alternative to the self-inflating bag is a free-flowing bag (e.g., Mapleson C Circuit), which is preferred by some clinicians, as it more readily facilitates detection of patient breathing and always provides 100% oxygen, even at high minute ventilation, in the absence of a reservoir. A perceived advantage of the self-inflating bag is that it enables the operator to provide positive pressure ventilation if there is no oxygen source available. However, because of the self-inflating feature, risk of unnoticed disconnect of the oxygen during the denitrogenation phase is possible. In contrast, a disconnect in a free-flowing bag will be immediately noticed. Maintenance of team situational awareness and proactive monitoring can minimize the possibility of a disconnect.

The one-way valve that prevents rebreathing of exhaled gases on the self-inflating bag should be held open during denitrogenation if low oxygen flows are used, as they may be during resuscitation of a patient with COVID-19.[11,12] Generally, flows higher than the patient's minute ventilation are recommended to prevent rebreathing of exhaled gases. An adequate mask seal is imperative and can be confirmed using bedside end-tidal capnography, which has become commonplace in many centers (see below).

Critically ill patients requiring intubation frequently demonstrate reduced minute ventilation and FRC, impaired baseline oxygenation, or increased metabolic rate. In these circumstances, even robust denitrogenation may not provide much of a safeguard against rapid desaturation during apnea. A reduced functional residual capacity (FRC) accentuates the problem in patients who are obese, recumbent, or pregnant, or who have atelectasis or splinting with pain.

High-flow nasal oxygenation (HFNO) and high-velocity nasal insufflation (HVNI) are two similar modes of oxygen delivery that have gained extensive use in recent years as a strategy to enhance respiratory mechanics in an effort to prevent the need for intubation and mechanical ventilation. These modes deliver humidified oxygen at flow rates up to 70 L/min and are generally well tolerated by awake patients. Use of HFNO during intubation has been evaluated as a strategy to reduce hypoxemia around the time of apnea and intubation in critically ill patients. A meta-analysis of seven studies, including six randomized controlled trials, demonstrated noninferiority of HFNO and a distinct benefit in patients will mild hypoxemia prior to intubation.[13] HFNO may reduce hypoxemia by a variety of mechanisms, including washout of dead space and stenting open of airways to facilitate apneic oxygenation. Patients with respiratory compromise are also frequently placed on noninvasive ventilation (NIV) modes such as Bi-PAP or CPAP. In these patients, the respiratory mechanics for denitrogenation prior to intubation are likely to be better if the noninvasive ventilation is maintained using 100% oxygen, rather than shifting to an alternative mode of ventilation, such as the self-inflating bag.[3]

Each of the above denitrogenation strategies frequently improves respiratory dynamics, decreases work of breathing, and, likely, reduces atelectasis. These effects reduce the extent of hypoxemia or hypercarbia prior to induction of apnea for intubation. The approach may be especially important in obese patients or challenging intubations. Use of HFNO and NIV in combination in selected patients can be efficacious.[14]

Patients in need of urgent or emergent airway management usually have not been fasting, and maintaining oxygenation using bag mask ventilation may be difficult due to the host of factors discussed above. Under these circumstances, rapid sequence induction (RSI) is most often utilized. The technique is designed to achieve conditions for intubation as quickly as possible and to reduce both aspiration risk and desaturation. The precise details of RSI may vary by institution, clinical setting, and local experience. The key features of RSI include administration of a rapidly acting sedative–hypnotic and muscle relaxant, elevation of the head of the bed, rapid achievement of intubating conditions in an effort to avoid the need for positive-pressure mask ventilation, and consideration of cricoid pressure to obstruct the reflux of gastric contents into the oropharynx. It is critical to be prepared to provide effective mask ventilation when indicated—typically in the setting of unanticipated difficult intubation or rapid desaturation after administration of sedative–hypnotic agents, before intubation can be accomplished.

MASK VENTILATION

Delivery of effective mask ventilation can be challenging, but it is a life-sustaining skill and intervention. When required, effective mask ventilation can be most reliably accomplished in most patients and clinical circumstances using a two-handed technique and the "triple maneuver."[15,16] This is particularly true given the high prevalence of obesity and obstructive sleep apnea. The triple maneuver (Fig. 145-5) employs mouth opening and mandibular advancement, combined with caudad tension on the mental protuberance and firm inward (not downward) pressure on the mask to achieve a seal. Transoral ventilation is more reliable in the sleeping or sedated patient than is transnasal intubation.

The velopharyngeal sphincter is a three-dimensional structure, located between the oral and nasal cavities, consisting of lateral and posterior pharyngeal walls and the soft palate. It is unsupported by cartilage. This area readily collapses with administration of sedative agents or muscle relaxants and may require substantial pressure to effectively re-expand. The lowest inflating pressures that can be used to achieve adequate tidal volumes should be employed so as to decrease air entry into the stomach. When mask ventilation is necessary during a rapid sequence intubation, cricoid pressure can be maintained if it allows effective ventilation. PEEP can be added as needed, but it will not be as effective as PEEP in the intubated patient. Factors contributing to difficult mask ventilation include facial hair, operator inexperience, use of one hand in critical settings, large neck circumference, history of sleep apnea, and lack of muscle relaxation or adequate sedation.

MASK VENTILATION ADJUNCTS

Challenging mask ventilation can often be overcome with use of an oral or nasal airway and, often, addition of muscle relaxants and paralytics, if not already administered. Oral and nasal airways can displace the tongue (oral airway) or nasal–oropharyngeal junction (nasal airway) from the airway. Artificial airways come in a variety of sizes and frequently, but not invariably, enhance the effectiveness of mask ventilation (Fig. 145-6). Artificial airways may cause significant injuries, such as bleeding, dental damage, or soft tissue trauma. In the unparalyzed or inadequately sedated patient, placement of an oral airway may induce vomiting and result in aspiration of gastric contents. Placement of a nasal airway along the floor of the nasal passage, on the side where the nasal septum is less obstructive, is useful in providing a passageway for both mask ventilation and nasal intubation, thereby avoiding trauma to the turbinates from the tip or cuff of the balloon or artificial airway. Once the choana is navigated, gentle passage through the nasopharynx should be feasible.

DIRECT LARYNGOSCOPY, VIDEOLARYNGOSCOPY, AND TRACHEAL INTUBATION

Chevalier Jackson, an otolaryngologist, is considered the father of bronchoscopy and laryngoscopy. He designed the first direct laryngoscope in 1903 (Fig. 145-7).[17] Traditional direct laryngoscopy

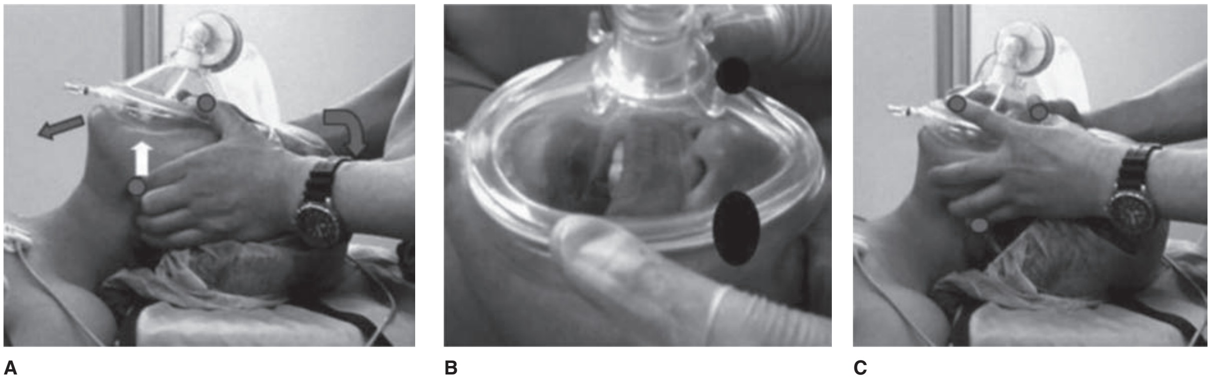

Figure 145-5 Triple airway maneuvers (mandible advancement, neck extension, and mouth opening) with two hands in the sniffing position. **A.** Only thumbs and forefingers are used for the triple airway maneuvers. **B.** Mouth opening is easily maintained in the triple maneuver approach. Mask is sealed with inward pressure toward the nose and gentle lifting into the mask. **C.** Mouth opening is often difficult using the common, two-hand clamshell technique. *(Reproduced with permission from Sato Y, Ikeda A, Ishikawa T, et al. How can we improve mask ventilation in patients with obstructive sleep apnea during anesthesia induction? J Anesth. 2013;27(1):152–156)*

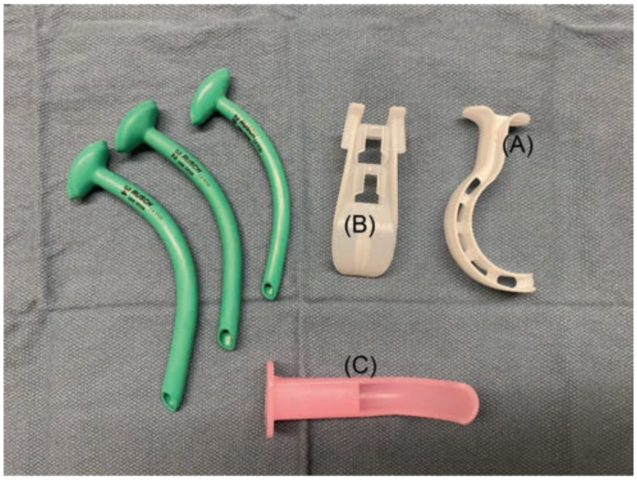

Figure 145-6 Nasal airways *(green)* in three sizes (28F, 32F, 34F). **A.** ventilating oral airway. Intubating oral airways through which ventilation and flexible fiberoptic intubation can be achieved, including Ovassapian breakaway airway (**B**) and Williams airway (**C**).

employs laryngoscope blades invented in the 1940s by Robert Miller, a Texas clinician, and Robert Macintosh, an Oxford professor. The curved Macintosh blade differed from previous models and was designed for insertion between the epiglottis and tongue. The Miller blade was an advance over similar straight blades; it was designed to pick up the epiglottis and expose the vocal cords (Fig. 145-1). Although many variants of the two blades are available today, including those with different angulations, prisms, and fiberoptic bundles, the Miller and Macintosh blades remain mainstays in the armamentarium for intubation (Fig. 145-8).

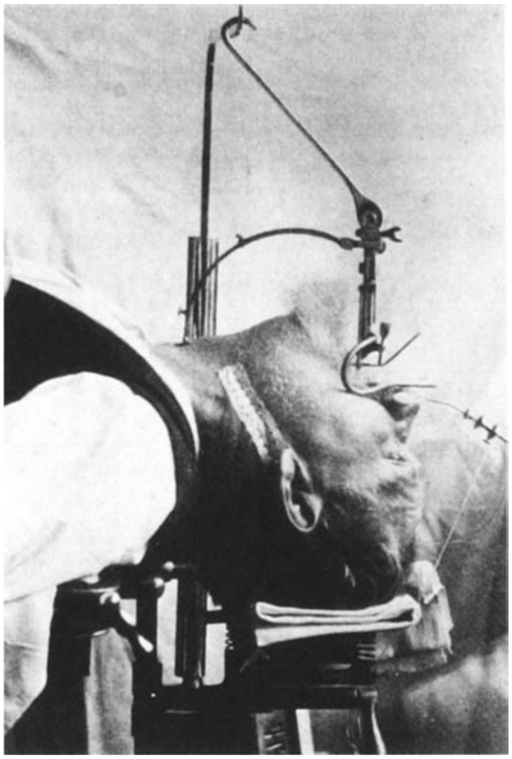

Figure 145-7 Killian's suspension microscope with a retrofitted, external, laryngeal counterpressure device. The head and neck position are incorrect; the occiput is below the shoulders. *(Reproduced with permission from Zeitels SM. Chevalier Jackson's contributions to direct laryngoscopy. J Voice. 1998;12(1):1–6.)*

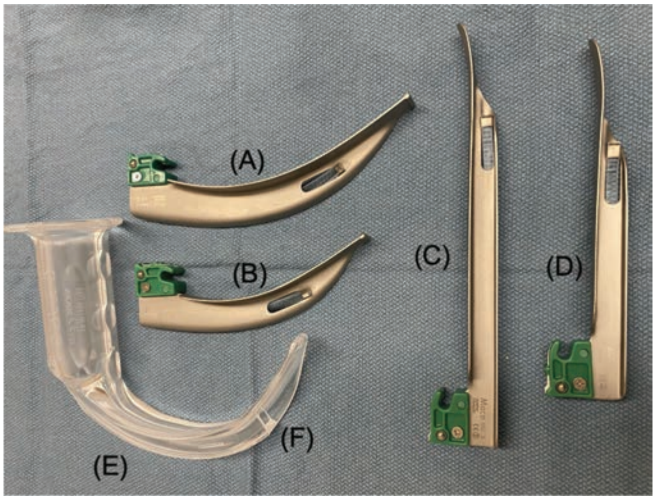

Figure 145-8 Commonly used laryngoscope blades. The curved MacIntosh blades in sizes 4 (**A**) and 3 (**B**) are placed into the vallecula. The straight Miller blades in sizes 3 (**C**) and 2 (**D**) are placed under the epiglottis. The hyperangulated blade **E** is used with a videolaryngoscope, usually in a difficult intubation scenario. The camera is positioned at point **F**. All blades shown come in single-use and re-usable formats.

Direct laryngoscopy applies perpendicularly oriented forces, along with tissue forces, to a laryngoscope blade in order to displace the tongue, epiglottis, and other soft tissues, and to facilitate alignment of the mouth, pharyngeal, and laryngeal axes (the "three axes") with the eye (Fig. 145-9). Head position likely plays an important role in the ability to achieve alignment, and various head elevation (see above)

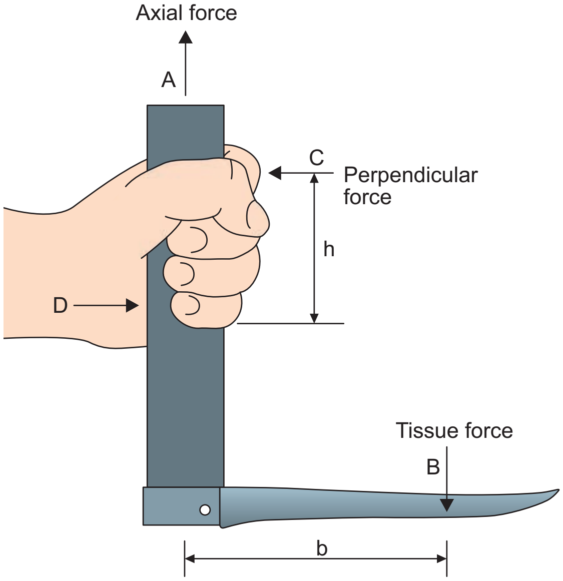

Figure 145-9 Laryngoscope in hand and straight blade attached, showing the lever arms and forces applied in direct laryngoscopy to visualize the glottis. Upward lift on the handle (**A**). This external force is resisted by a normal force from the patient's tongue. The two forces perpendicular to the handle are also separated by a moment arm (**h**). The two forces parallel to the handle do not act on the same point on the laryngoscope, but are separated by a moment arm (**b**). Force acting around a moment arm results in torque. The laryngoscopist's upper fingers pull back on the handle with force that is resisted by the palm (**D**). *(Reproduced with permission from Hastings RH, Hon ED, Nghiem C, et al. Force, torque, and stress relaxation with direct laryngoscopy. Anesth Analg. 1996;82(3):456–461.)*

or “sniffing” positions have been described to optimize chances of success.

MRI studies in awake subjects in the sniffing position (Fig. 145-10) suggest that the hypothetical axis alignment is actually difficult to achieve.[17] Once the mouth is scissored open, using a curved Macintosh blade the tongue is displaced laterally with the flange as the blade is gradually advanced into the vallecula. A straight Miller or tubular surgical laryngoscope is advanced over the tongue and under the epiglottis. Blade choice is often related to the comfort and experience of the intubator, but straight blades can be particularly helpful with a large, floppy epiglottis or an anteriorly located glottis. A standard grading system (modified Cormack–Lehane system) is used to describe the degree to which the glottic structures can be visualized during laryngoscopy and is a critical component of the airway procedure note (Fig. 145-11). This system is not ideal, as it is subject to interpretation and has led to modifications of grade 2 in the Cormack–Lehane classification system. An alternative and more descriptive score, percentage of glottic opening (POGO) visualized, has been advocated and validated, but it is not widely adopted.[18]

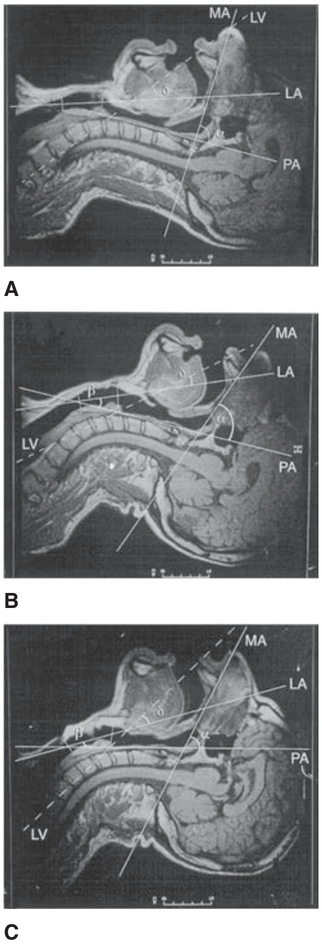

Figure 145-10 Evolution of the four axes that hypothetically need to be aligned for successful visualization of the glottis by direct laryngoscopy (mouth axis **[MA]**, pharyngeal axis **[PA]**, laryngeal axis **[LA]**, line of vision **[LV]**), and the α, β, and δ angles in the three head positions. Magnetic resonance images are shown for a single patient. **A.** Neutral position. **B.** Simple head extension. **C.** “Sniffing” position—a combination of flexion of the neck and extension of the head. *(Reproduced with permission from Adnet F, Borron SW, Dumas JL, et al. Study of the “sniffing position” by magnetic resonance imaging. Anesthesiology. 2001;94(1):83–86.)*

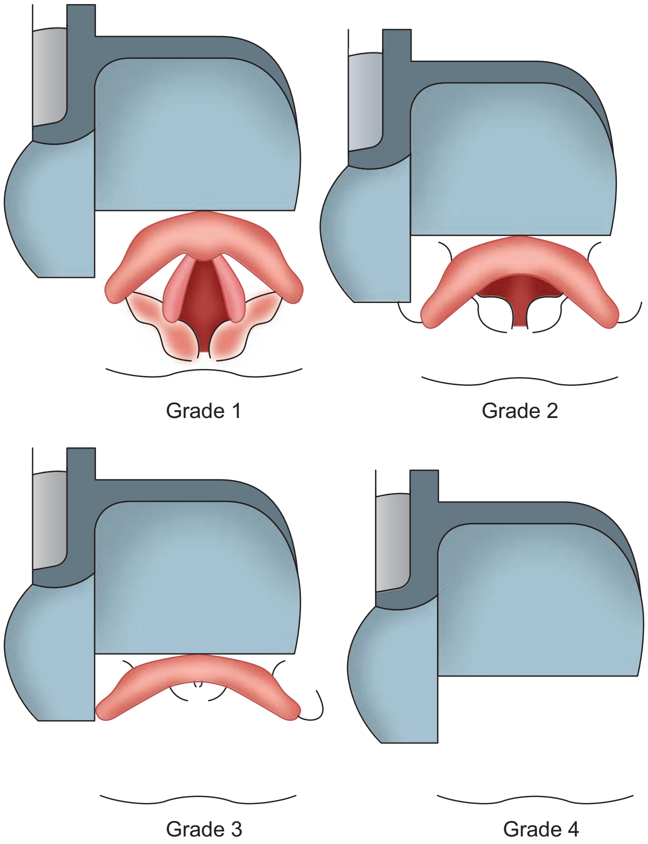

Figure 145-11 Modified Cormack–Lehane score. Laryngoscopic views of the Cormack–Lehane grades. Grade 1: 100% of vocal cords completely visualized. Grade 2: Less than 100% of vocal cords visualized. Some divide this into 2a with full arytenoids visible, and 2b with only the base of the arytenoids visible. Grade 3: Only epiglottis visualized. Grade 4: Epiglottis not visualized. This score can be compared with the POGO score referenced in the text.

Mastery of technique in traditional laryngoscopy is important as a foundational skill. However, the approach is fraught with challenges that are made even more complicated in emergent settings by the presence of secretions, coagulopathy, episodes of rapid desaturation, and highly variable patient anatomy. A fraction of patients will have upper airways difficult or impossible to visualize using direct laryngoscopy, thereby necessitating rapid transition to alternative approaches. Small mouth opening, radiation-induced fibrosis, disease of the temporomandibular joint, excess soft tissue, short mentohyoid distance, airway edema, crowded or prominent incisors, and oropharyngeal pathology may all contribute to the difficulty. For these reasons, intubation technique has rapidly shifted away from direct laryngoscopy using Miller and Macintosh blades to video-assisted indirect laryngoscopy (VAL). Ironically, this is a modern, “high-tech” approach to the indirect mirror-and-candle approach to visualizing the vocal cords taken by some of the earliest innovators. In highly resourced environments, use of VAL for emergency intubation has become routine, and this trend is certain to continue.

VAL uses a recessed light source and camera to produce an indirect view of the larynx. The view is panoramic and visible on a screen.[18] This can be advantageous to the operator in identifying anatomic landmarks and anatomic variants, or pathology that may encumber intubation. VAL also allows the entire clinical team to view the intubation and provide clinical assessment, advice, and assistance, if needed. With most devices the procedure can be video recorded for later reference or for permanently capturing airway anatomy in the patient record. VAL has been associated with fewer attempts to achieve successful intubation, but in some studies has been associated with a longer time to achieve intubation. VAL may enhance the glottic view, especially in more challenging circumstances, such as in patients with limited mouth opening or decreased cervical mobility. Many varieties of VAL technology are commercially available, and different devices may lead to variations in practitioner success rates in the absence of structured training and practice.

Two general classes of VAL scope blades are available: (1) blades with an integrated channel for passage of the endotracheal tube, and (2) unchanneled blades that allow free mobility of the tube in the oropharynx.[18] Many devices offer a variety of blades including, for example, a hyperangulated blade able to enable visualization of an anteriorly positioned glottic inlet. A hyperangulated blade (Fig. 145-8E) is frequently used to rescue failed traditional laryngoscopy. Currently, many VAL laryngoscopes are also equipped with blades that mimic traditional Macintosh or Miller blades. These scopes can be used for teaching and practicing direct laryngoscopy; the screen can be turned off or away from the intubator, while still allowing transition to the video approach, if needed, without delay or need for repeat laryngoscopy.

VAL is not a panacea; difficult and failed intubations are a present-day reality. For example, VAL is challenging in the bloody or secretion-filled airway. Tube passage or alignment, despite excellent glottic view, has been noted as a significant problem encountered infrequently with direct laryngoscopy. The operator's status as a novice or expert when using a specific device can be crucial.[19] Hybrid techniques that employ flexible fiberoptic bronchoscopy and VAL can also be of utility in these situations. Likewise, a gum elastic bougie with an angulated tip can sometimes be placed into the trachea and used as a guide to VAL-assisted intubation. Use of the bougie can also be considered when a "blind" intubation is needed due to inadequate view of the glottic structures.

Pharyngeal soft-tissue injury by the blade or tube due to fixation of the operator on the screen, instead of the mouth, may occur and can be severe.[20] Care must be taken to advance the tube into the oropharynx under direct vision, and then to look at the screen as the tube approaches the glottic opening. Disposable and reusable versions of a blade can have different properties, including size and thickness, that contribute to challenges in switching from one to the other. As was learned during the COVID-19 pandemic, supply chains can be unexpectedly disrupted, and reliance on a single platform can be problematic under these circumstances. Use of a single type of VAL throughout all clinical areas of a hospital may be of benefit, providing for universal familiarity, equipment exchangeability, and ease of maintenance.

Most intubations use a standard endotracheal tube with a high-volume, low-pressure cuff. All single-lumen tubes can connect to any standard ventilation device. Tubes come in a wide range of sizes. Single-lumen tubes are described by the size of the inner diameter (in mm). A larger-diameter tube will be necessary for therapeutic bronchoscopy, and a smaller-diameter tube might be used for patients with airway pathology or narrowing. Most also have a radio-opaque stripe that permits tube localization on a chest radiograph. Specialized tubes, including wire-reinforced, double-lumen, and metal laser tubes, can be considered in certain special situations. Importantly, use of special-purpose endotracheal tubes should be limited in the intensive care setting. Lack of staff familiarity with such tubes poses a significant latent safety threat. Tubes with tapered cuffs or subglottic suction (e.g., Hi-Lo tubes) are endorsed by some clinicians for prolonged intubation, as they may decrease the risk of ventilator-associated pneumonia. The Parker Flex-Tip tube is a good alternative to a flexible fiberoptic or blind intubation, as the curved bevel is designed to decrease impingement of the tube on the right arytenoid during blind passage over the scope.[21]

Proper location of the tube in the trachea must be confirmed after intubation by measurement of end-tidal carbon dioxide (using a colorimetric, in-line, or portable handheld device) or direct inspection of the endotracheal tube by fiberoptic inspection when carbon dioxide detection is not feasible. Auscultation of both lungs should be performed to rule out mainstem intubation. The high-volume, low-pressure cuff should be inflated with the minimum pressure required to eliminate a leak, and the pressure should be monitored periodically. An overinflated cuff produces ischemic injury to adjacent tissues. Ideally, the cuff should not be inflated high in the airway, since this can lead to significant tracheal injury resulting in stenosis or unintended extubation during patient movement. Optimal tube position within the trachea can be further confirmed with a chest radiograph—the best way to confirm that the endotracheal tube is not too shallow. Prolonged intubation with a cuff inflated too high in the airway can contribute to tracheal stenosis, long-term morbidity, and inadvertent tube dislodgement during repositioning for clinical examinations or procedures.

In cases where intubation is predicted to be difficult, based on history or factors previously discussed, awake or sedated flexible bronchoscopic intubation may provide a measure of safety. Spontaneous respiration and airway tone are largely maintained with this approach. Depending on the level of concern, this may be done with minimal or moderate sedation, administration of an antisialagogue, and application of topical lidocaine to blunt airway reflexes. If the patient already demonstrates airway obstruction, the procedure may need to be done using no sedation and only topical, local anesthesia to maintain spontaneous ventilation. In such cases, intubation by clinicians with advanced airway expertise should be considered. Rapid access to an intubating flexible fiberoptic bronchoscope is an important backup for all intubations.

In rare cases, intubation may be impractical, and ventilation may be compromised, for example in the presence of distal tracheal obstructions or compressive, low-midline neck masses, such as massive thyroid goiters (Fig. 145-2). When the possibility of a difficult airway is entertained, the potential anatomic difficulty of surgical front-of-neck access must also be evaluated, since a surgical airway is also not a guaranteed salvage option. In such cases, interim use

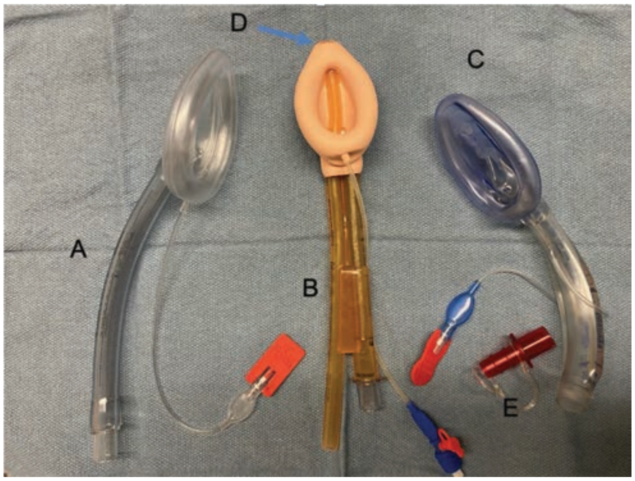

Figure 145-12 Different varieties of supraglottic airways. **A.** Classic disposable LMA 5 with non-removable connector. **B.** Second-generation reusable LMA Proseal. The second lumen transits to the tip of the cuff (**D**), which is placed into the proximal esophagus and can be used to evacuate gastric contents with an orogastric tube. Higher ventilating pressures can also be achieved due to the larger cuff. **C.** Air-Q LMA with a removable connector (**E**). The curve is designed to facilitate placement, and the removable cuff and other features allow for trans-LMA flexible fiberoptic intubation.

of heliox and proactive planning for establishing an airway in the operating room, using rigid bronchoscopy and possibly ECMO, may be required. When intubation fails due to an inadequate view or difficulty with tube passage, rapid transition to a supraglottic airway as a temporary or definitive ventilation conduit is indicated.

SUPRAGLOTTIC AIRWAYS

In recent decades an entire class of airway devices, known as supraglottic airways (SGAs), has revolutionized airway management and airway safety. These devices come in many varieties; the most common class is the laryngeal mask airway (LMA) (Fig. 145-12).[22] The distal tip of the LMA sits in the proximal esophagus, while the LMA cuff forms a supraglottic seal with the arytenoids. Placement is relatively straightforward and involves advancing the lubricated cuff into the back of the oropharynx and then applying gentle pressure to the tube to advance to the upper end of the esophagus (Fig. 145-13).

Different types of SGA may require slightly different placement technique. SGAs are extremely valuable for a number of reasons:

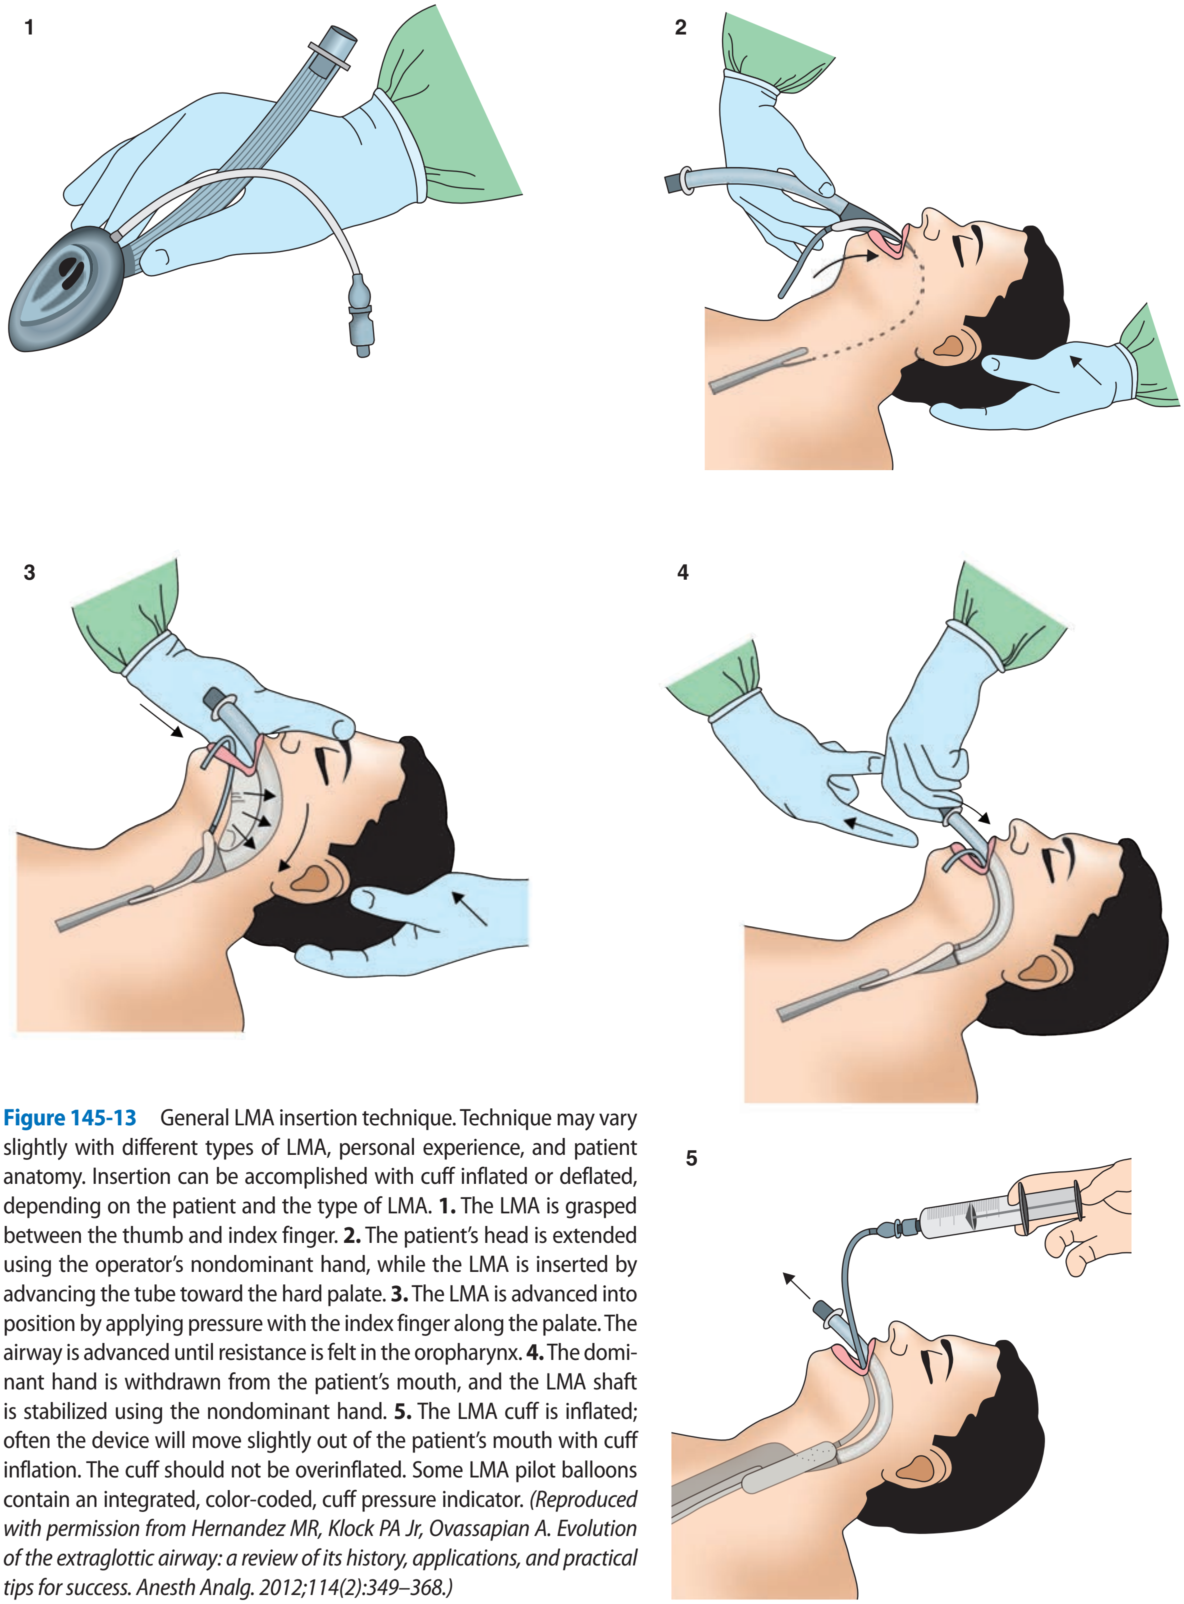

Figure 145-13 General LMA insertion technique. Technique may vary slightly with different types of LMA, personal experience, and patient anatomy. Insertion can be accomplished with cuff inflated or deflated, depending on the patient and the type of LMA. **1.** The LMA is grasped between the thumb and index finger. **2.** The patient's head is extended using the operator's nondominant hand, while the LMA is inserted by advancing the tube toward the hard palate. **3.** The LMA is advanced into position by applying pressure with the index finger along the palate. The airway is advanced until resistance is felt in the oropharynx. **4.** The dominant hand is withdrawn from the patient's mouth, and the LMA shaft is stabilized using the nondominant hand. **5.** The LMA cuff is inflated; often the device will move slightly out of the patient's mouth with cuff inflation. The cuff should not be overinflated. Some LMA pilot balloons contain an integrated, color-coded, cuff pressure indicator. *(Reproduced with permission from Hernandez MR, Klock PA Jr, Ovassapian A. Evolution of the extraglottic airway: a review of its history, applications, and practical tips for success. Anesth Analg. 2012;114(2):349–368.)*

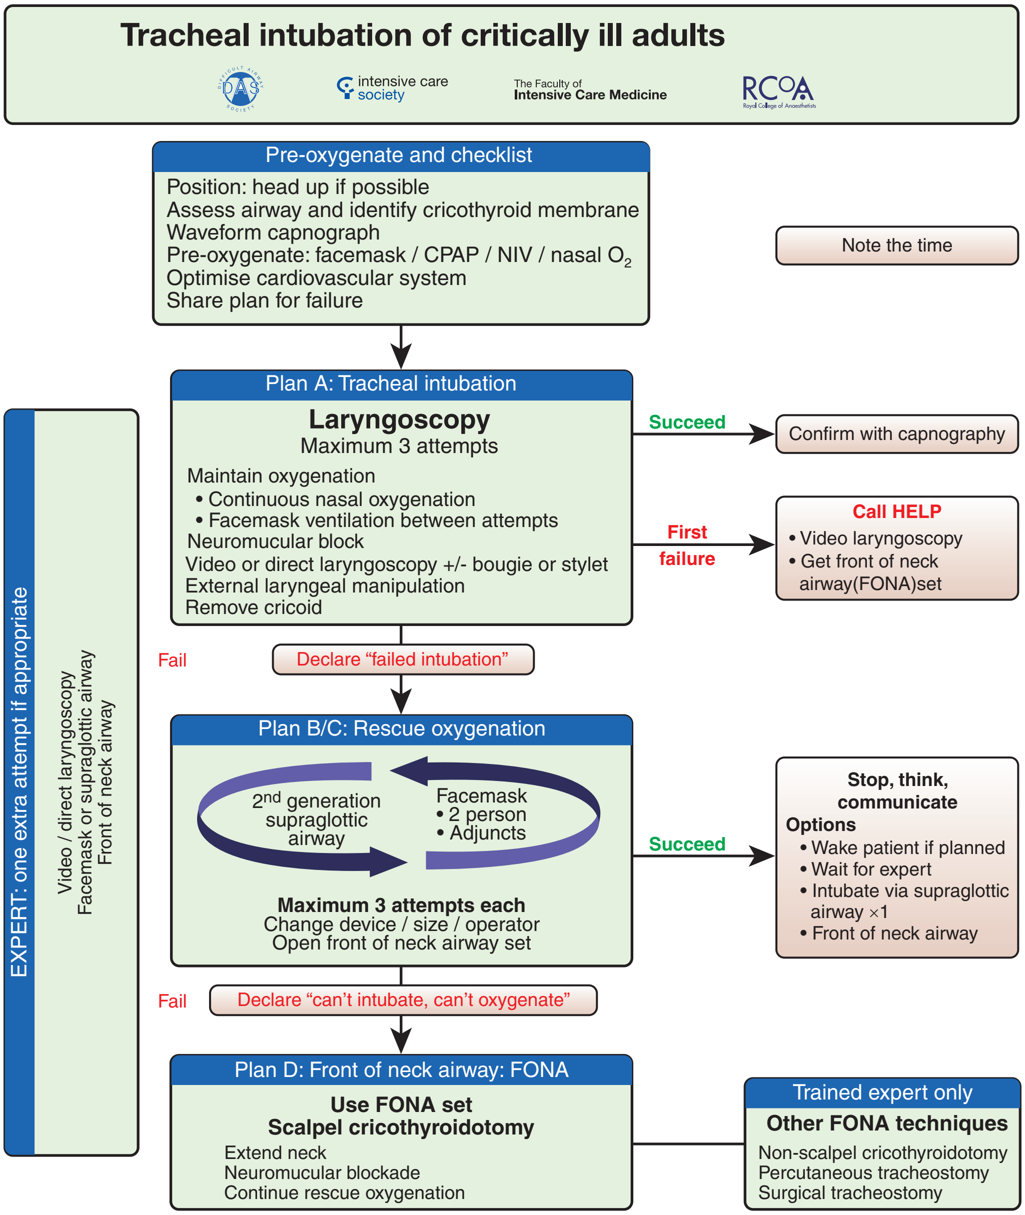
(1) they are placed blindly (i.e., no need to visualize the glottis) and can be used in emergencies, with operators having limited training; (2) they seat well enough to oxygenate the vast majority of patients, even those having difficult intubations; (3) they are disposable; and (4) they may serve as a conduit for positive-pressure ventilation, intubation, evacuation of gastric contents, airway suctioning, and bronchoscopy.

SGAs are used as the primary airway for general anesthesia in a large range of procedures, including bronchoscopy, because they are safe, are generally easy to place, and provide an excellent conduit for bronchoscope passage. The primary limitations of SGAs are that they do not protect against aspiration or laryngospasm. Positive-pressure ventilation is possible (generally at pressures <25 cm H_2O); in difficult mask ventilation settings, rapid transition to an SGA for oxygenation and ventilation may be life-sustaining until definitive airway management is possible. Many variants of the LMA can also serve as a conduit for blind or fiber-optically guided intubation. So-called second-generation SGAs, such as the LMA Pro-seal, LMA supreme, Air-Q, Gastro, and I-Gel, include a variety of features, such as enhanced cuffs for improved airway protection and higher-pressure ventilation. They also include a second esophageal lumen at the distal tip of the cuff for evacuation of gastric contents. In the past, devices such as the Combitube and the King Airway were used to facilitate blind airway management in the field or in other emergent circumstances. The LMA has largely replaced these alternatives due to its ease of use and demonstrated effectiveness.

THE DIFFICULT AIRWAY

The definition of a difficult airway is often context- and provider-dependent. Widespread adoption of VAL has complicated the definition. Generally, difficulty keeping the patient's saturation at or above about 90% using mask ventilation (assuming the patient has normal pulmonary function), the need for more than three intubation attempts, or the need to use a specialized intubation technique or advanced equipment warrants designation as a difficult airway. The Difficult Airway Society (DAS)[23] and the American Society of Anesthesiologists[24] have each published difficult airway guidelines, including embedded algorithms and checklists (Fig. 145-14) that are



Tracheal intubation of critically ill adults
DAS
intensive care society
The Faculty of Intensive Care Medicine
RCoA
Pre-oxygenate and checklist
Position: head up if possible
Assess airway and identify cricothyroid membrane
Waveform capnograph
Pre-oxygenate: facemask / CPAP / NIV / nasal O2
Optimise cardiovascular system
Share plan for failure
Note the time
Plan A: Tracheal intubation
Laryngoscopy
Maximum 3 attempts
Maintain oxygenation
• Continuous nasal oxygenation
• Facemask ventilation between attempts
Neuromucular block
Video or direct laryngoscopy +/- bougie or stylet
External laryngeal manipulation
Remove cricoid
Succeed
Confirm with capnography
First failure
Call HELP
• Video laryngoscopy
• Get front of neck airway(FONA)set
Fail
Declare "failed intubation"
Plan B/C: Rescue oxygenation
2nd generation supraglottic airway
Facemask
• 2 person
• Adjuncts
Maximum 3 attempts each
Change device / size / operator
Open front of neck airway set
Succeed
Stop, think, communicate
Options
• Wake patient if planned
• Wait for expert
• Intubate via supraglottic airway ×1
• Front of neck airway
Fail
Declare "can't intubate, can't oxygenate"
Plan D: Front of neck airway: FONA
Use FONA set
Scalpel cricothyroidotomy
Extend neck
Neuromucular blockade
Continue rescue oxygenation
Trained expert only
Other FONA techniques
Non-scalpel cricothyroidotomy
Percutaneous tracheostomy
Surgical tracheostomy
EXPERT: one extra attempt if appropriate
Video / direct laryngoscopy
Facemask or supraglottic airway
Front of neck airway

periodically reviewed and updated. The DAS has gone one step farther and developed guidelines focused on intubation of the critically ill patient, acknowledging the unique patient characteristics, setting, and teams in the intensive care unit.[25] The use of difficult airway alerts in the electronic health record, patient bracelets, and identification of response clinical teams (see below) have become common.

Anyone participating in upper airway management should be familiar with these guidelines, have the necessary skill and equipment to implement them as necessary, and reference them explicitly when difficulty is anticipated or encountered. Difficult airway guidelines and national audits, such as the UK NAP4, reflect the critical aspects of planning, appropriate staffing, equipment availability, and human factors (i.e., communication, situation monitoring, and teamwork) contributing to success or failure of establishing an airway.[26] Human factors, for example, come into play when one member of the team suggests a surgical front-of-neck access after several failed intubation attempts, but the intubators are so focused on successfully managing the airway that they are unable to hear, process, or endorse the suggestion.

The Vortex is one structured approach that brings together difficult airway technique, cognitive aids, and teamwork (Fig. 145-15).[27] The Vortex visual "cone" is designed to reinforce that mask ventilation, supraglottic devices, and endotracheal tubes should all be considered for patient oxygenation during the course of airway management, particularly as challenges occur with the primary strategy. Fixation errors in which teams struggle to adjust a plan—for example, failure to intubate using an 8.0-mm endotracheal tube for bronchoscopy when a 6.0-mm tube would have worked—may lead to poor outcomes. Human factors are as relevant as technical skills in airway management, including open team communication before, during, and after upper airway management, especially in the critical care setting. This can be accomplished in a variety of ways, including use of periprocedural huddles, checklists, patient simulation, and readily accessible electronic documentation by all clinicians.

DIFFICULT AIRWAY EQUIPMENT

Availability of advanced equipment for difficult airways is essential. Difficult airway carts centralize specialized airway equipment in one location and can be rapidly mobilized to other areas as needed. The specific equipment on the cart is customized to local provider and patient needs, but it generally includes a fiber-optic scope and screen, a range of tube sizes and types, intubating oral airways, ventilating airways, exchange catheters and bougies, forceps, alternative laryngoscopes, supraglottic airways, sets for emergent scalpel use and percutaneous front-of-neck access, and cognitive aids such as difficult airway algorithms.[28] Operationalizing difficult airway trolleys requires careful planning with regard to the equipment, a process to check and maintain the supplies, a system to deliver the equipment quickly when needed, and working familiarity of staff with the process.

Difficult or surgical airway response systems are another potential resource to be considered in high-acuity centers. These systems involve an integrated alert call to bring difficult airway equipment, support staff, and a surgeon capable of front-of-neck access quickly to the bedside through an integrated activation process.[29] Such a system can be useful not only for failed intubation, but also for urgent interdisciplinary, interprofessional consultation on "at-risk" airways.

Figure 145-15 The VORTEX approach to intubation. The approach is designed to help teams maintain situational awareness when a difficult intubation is encountered. It also provides visual cues for continued advancement along the difficult airway algorithm, using adjuncts like the LMA. *(Reproduced with permission Chrimes N. The Vortex: a universal 'high-acuity implementation tool' for emergency airway management. Br J Anaesth. 2016;117 Suppl 1:i20–i27.)*

A patient with a prior difficult intubation should be labelled as such using a bracelet identifier, an alert in the electronic health record, and notation in a discharge summary provided to the patient for future reference. Ideally, the information necessary to manage the airway is readily available to emergency response teams.

As discussed, airway challenges create great stress in the clinical environment. The wide range of pathology and situations requires a multidisciplinary approach to management. Airway crises may arise de novo or in patients with existing airways, including tracheostomies. Many centers have organized difficult airway teams that bring the key players in the hospital together to address complex scenarios.[30,31]

Discussion of some of the system initiatives that can be beneficial in managing planned and unplanned airway scenarios that may challenge the members of a multidisciplinary team is worthwhile. Such programs include, for example, the "Multidisciplinary Airway Rapid Response Team" (MAART), which, when activated, brings personnel with requisite expertise and special equipment to the scene of an airway emergency. This higher level of emergency response is beneficial for patients who have been previously identified as having a difficult airway. Patients who have been deemed "difficult" receive a special bracelet and are specifically identified in the electronic medical record. In addition, the "MAART" can be activated whenever there is difficulty securing an airway, even when the difficult airway designation has not been made previously. Furthermore, patients who are deemed high risk are so labeled following intubation, creating an opportunity for planning an "extubation" protocol. These patients have a sticker placed on their ET tube pilot balloon, and chart documentation defines the circumstances, personnel, and protocols needed for extubation.

Finally, since tracheostomy is such a frequent trigger of airway emergencies, use of tracheostomy "cards" should be considered as a way of indicating the type and timing of tracheostomy (open or percutaneous) or laryngectomy. This approach was pioneered in the United Kingdom and incorporates a first- and expert-responder algorithm to help manage acute emergencies.[32,33]

FAILED AIRWAY MANAGEMENT AND EMERGENCY FRONT-OF-NECK ACCESS

The first-line surgical airway for the "cannot oxygenate/ventilate, cannot intubate" scenario is to perform a cricothyroidotomy. The procedure is faster and safer than emergent tracheostomy, as long as the patient's pathology is not subglottic in location. Cricothyroidotomy also has a lower complication rate than emergent tracheotomy.[34] Ideally, if the procedure becomes necessary, the airway team has already been activated. Oxygenation should be given at 100% concentration and placement of an LMA attempted while front-of-neck access is being secured. The neck is extended, and the cricothyroid membrane is palpated using a laryngeal "handshake" (Fig. 145-16 Upper Panel). When the anatomy is not clear, a vertical incision is made over the membrane down to the larynx to avoid anterior jugular veins; care must be exercised to avoid incising thyroid tissue. A horizontal incision is then made through the cricothyroid membrane, and the scalpel is rotated 90 degrees so the tip of the blade is toward the patient's feet (Fig. 145-16 Lower Panel).[35] Bleeding may occur from the cricothyroid artery, but it should not prevent airway entry. The incision is then held open, which may facilitate tamponade of any bleeding that does occur, and an endotracheal tube is placed, ideally over a bougie or tube exchange catheter, if available. The cuff is inflated, and ET tube placement is confirmed with auscultation, capnography, and observation of patient chest rise. Bronchoscopy should be considered in assuring that the tube is situated just above the carina. If the cricothyroid membrane is not easily palpable, the vertical skin incision should be longer, and palpation of the membrane repeated, once it is exposed.

Ultrasound provides a quick, portable way to evaluate the airway, and it may be helpful in guiding difficult surgical airway access.[36,37] In cases of large laryngeal masses, where there may also be obstruction at the subglottic or tracheal levels, the preferred emergency surgical airway may be tracheostomy. Additionally, relative contraindications to cricothyroidotomy include age younger than 10 years, severe neck trauma, expanding hematoma, and preexisting laryngeal disease, such as cancer with subglottic extension. Under these circumstances, a planned urgent, rather than emergent, tracheostomy is preferred. Emergency tracheostomy has a high incidence of complications. For patients who have had prior tracheostomy, incision through the scar and use of a Kerrison rongeur to enlarge the tracheal opening may be safer than uncontrolled lateral dissection in scar tissue, which may cause excessive bleeding.

In general, emergency cricothyroidotomy should be converted to a tracheostomy as soon as the patient is stable enough for transfer to the operating room. While there may be a role for decannulation in some patients (if it can be done within a few days), rather than conversion (assuming reasonable confidence that the procedure was done correctly), there is some risk of laryngeal complications from this approach. This is especially true if the original procedure was done emergently and performed by a less experienced operator.[38] Notably, elective cricothyroidotomy for oral, pharyngeal, and laryngeal procedures and for head and neck trauma has been largely abandoned in favor of elective tracheostomy.

TRACHEOSTOMY: HISTORY AND INDICATIONS

The standard of care for establishing an elective surgical airway is tracheostomy. The procedure is indicated for patients who have the need for prolonged mechanical ventilation or in whom upper airway obstruction is anticipated for at least 7 to 10 days. Classic examples of its use for airway obstruction include supraglottic infection or tumor, obstructive sleep apnea, angioedema, and bilateral vocal cord paralysis; however, many of these conditions can be managed without tracheostomy. The procedure is also used in facial trauma when surgery is required and where neither oral nor nasal tubes can be safely secured. Finally, tracheostomy is sometimes used to manage chronic aspiration.

Practically speaking, the terms *tracheostomy* and *tracheotomy* are interchangeable. However, strictly speaking, distinction arises with procedures that intentionally create more permanent stomas. While tracheostomy is performed during partial laryngectomy, the preferred term for tracheal access performed during a total laryngectomy is tracheostomy or *laryngectomy stoma*. Important to note is that patients who have a total laryngectomy stoma cannot be ventilated, oxygenated, or intubated through the mouth or nose, since the trachea is sutured directly to the skin. This represents a critical issue that must be recognized during airway emergencies.

Tracheostomy, although recognized as far back as the time of the ancient Egyptians, did not become a routine surgical procedure until the late 19th century. In 1909, Chevalier Jackson published a landmark work that defined what we know as the current indications for the technique and postoperative management.[39] Most tracheostomies are performed on critically ill, intubated patients. Tracheostomy and removal of the endotracheal tube decreases the risk of long-term laryngeal complications, decreases the need for sedation in mechanically ventilated patients, aids patient liberation from mechanical ventilation, and facilitates initiation of oral intake and phonation. Percutaneous tracheostomy has rapidly become the method of choice in the intensive care unit and is associated with acceptable intraoperative and postoperative complication rates when performed by experienced individuals in the correct context. While open tracheostomy at the bedside is feasible, percutaneous tracheostomy is the most commonly utilized technique in most institutions. Its major benefit is elimination of the need to transport critically ill patients to the operating room.

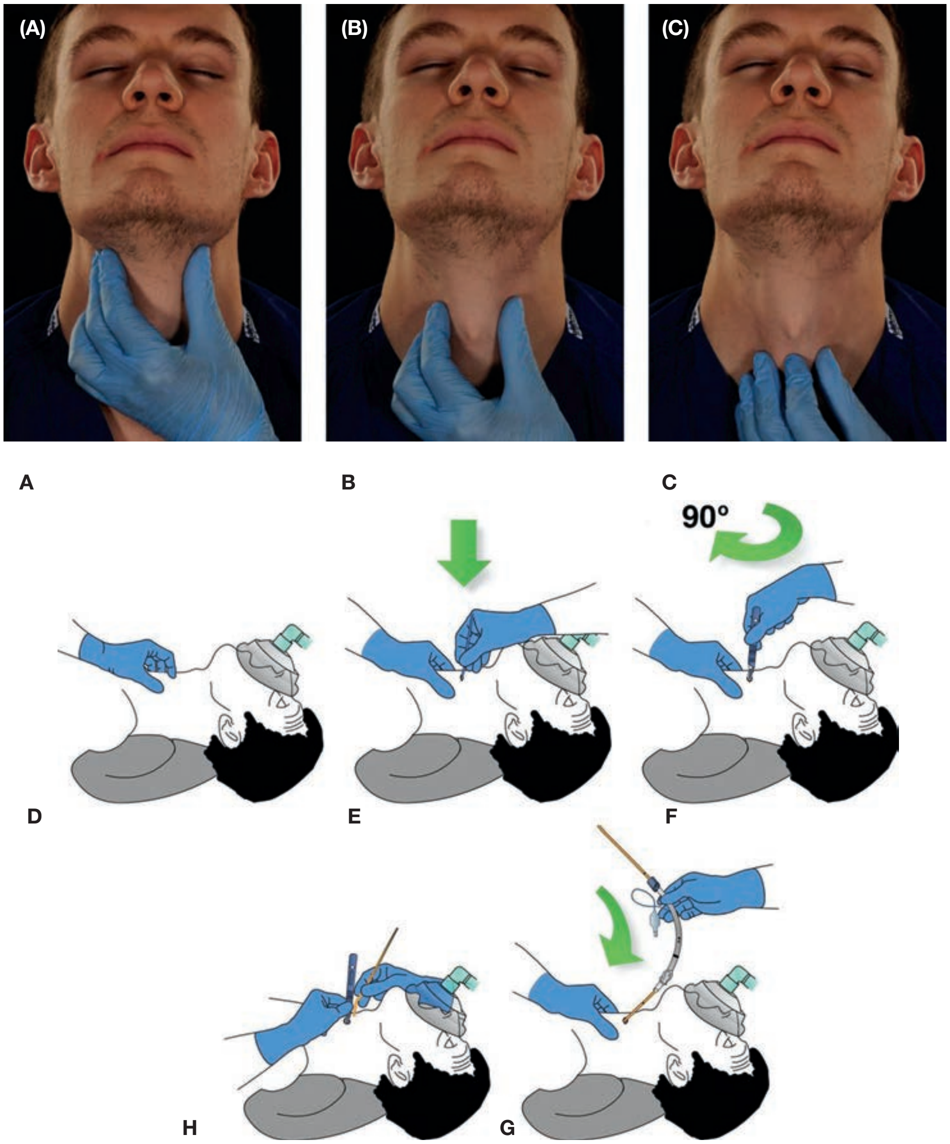

Figure 145-16 **Upper Panel.** The laryngeal handshake. **A.** The index finger and thumb of the nondominant hand grasp the top of the larynx and roll it from side to side. **B.** The fingers and thumb slide down over the thyroid laminae. **C.** Middle finger and thumb rest on the cricoid cartilage, with the index finger palpating the cricothyroid membrane. **Lower Panel.** Cricothyroidotomy technique. **D.** If the cricothyroid membrane can be palpated as in the upper panel: **E.** A horizontal scalpel incision is made through skin and cricothyroid membrane with blade facing towards operator. **F.** Scalpel is rotated 90 degrees towards the feet. **G.** The belly of the blade is used to stent the incision open by pulling towards operator to allow the bougie to slide along the medial aspect of the blade into the trachea. **H.** The tube is inserted into the trachea over the bougie. Note: If the cricothyroid *cannot* be palpated, as shown in the upper panel, an 8- to 10-cm incision is made in the midline and the laryngeal handshake performed after blunt dissection in order to identify the larynx. *(Reproduced with permission from Frerk C, Mitchell VS, McNarry AF, et al. Difficult Airway Society 2015 guidelines for management of unanticipated difficult intubation in adults. Br J Anaesth. 2015;115(6):827–848.)*

In December 2011, the American Academy of Otolaryngology–Head and Neck Surgery developed a series of consensus statements regarding tracheostomy, to which the reader is referred. Many are described below. A great deal of work is yet to be done in standardizing the perioperative care of patients with tracheostomies.

OPEN TRACHEOSTOMY

Open tracheostomy is defined as a tracheostomy in which the incision is made as the initial step. The incision may be vertical or horizontal, and it may require modification if done in a patient with an existing scar from prior surgery, including prior tracheostomy. The patient's neck should be extended, and the major landmarks palpated (including thyroid cartilage, cricoid cartilage, and sternal notch). A horizontal incision is preferred if the procedure is not urgent. In general, the incision should be approximately 5 mm to 1 cm below the level of the cricoid cartilage and approximately 2 cm above the sternal notch. The length is determined by the estimated depth of the cricoid, but it usually is about 2 to 3 cm.

Most of the time, the procedure is performed with the patient intubated and under general anesthesia. The skin and subcutaneous tissues are divided, and then the fascia dividing the strap muscles is incised vertically to expose the cricoid cartilage. Care should be taken to avoid the anterior jugular veins, which may sometimes be quite close to the midline. Often the thyroid isthmus lies in close proximity; most prefer to divide it with cautery to avoid subsequent obstruction of the airway if accidental decannulation occurs. A cricoid hook may be used to elevate the larynx. The soft tissue in the pretracheal area is divided and then bluntly dissected using a

Kittner. Bleeding is controlled using cautery, as needed. Ideally, the first three tracheal rings are exposed. Our preference is to perform a Bjork-style flap in most cases of open tracheostomy.

Once we are prepared to enter the airway, we alert the anesthesiology team. The tape or suture that secures the endotracheal tube is divided and the cuff is deflated. It is preferable to decrease the flow of oxygen in the event cautery is required again after the airway is entered. The tube may be advanced beyond the site of entry, or the incision may be made with the cuff deflated to avoid injuring the cuff. By pushing the tube cuff distal to the tracheostomy site, the cuff may be reinflated so that ventilation may resume during preparation of the Bjork flap. The Bjork flap is created by incising between the second and third tracheal rings; the inferiorly based tracheal ring flap of the third ring is created by making lateral cuts. Care should be taken to avoid going too far laterally with the lateral cuts to avoid an unstable trachea and, potentially, creation of an "A-frame" deformity that can lead to tracheal stenosis. The inferiorly based tracheal ring flap is then secured to the inferior skin using a single absorbable suture. This reduces the risk of a false passage in the event of accidental decannulation postoperatively, requiring urgent tube reinsertion. In our experience, the risk of tracheocutaneous fistula is very low, and most stomas heal after decannulation unless the stoma has been irradiated.

Subsequently, the cuff is again deflated, the tube is pulled back so that the tip is just visible above the tracheostomy site, and a cuffed tracheostomy tube is placed. The inner cannula is inserted, the tracheostomy cuff inflated, the ventilator connected, and adequate ventilation confirmed before the endotracheal tube is removed from the larynx. Finally, the tube is secured bilaterally, both superiorly and inferiorly, with permanent sutures from the skin to the tracheal tube flange; a tracheostomy tie is placed.

In case of prior tracheostomy, surgical identification of the cricoid may be difficult, and creation of a Bjork flap may be challenging. However, the scar over the trachea generally leads directly to the airway, so one useful technique is performing the procedure as technically similar to what was described above. If the trachea is entered at the site of prior tracheostomy and further dissection is difficult, a Kerrison rongeur can be used to safely enlarge the opening to allow insertion of the tube, without risking extensive dissection into scar tissue.

If the procedure is performed under local anesthesia, for example, in the setting of a marginal airway, use of a clear head frame to preclude the surgical drape from directly covering the patient's head allows the anesthesiologist to communicate with the patient, to titrate sedation safely, and to provide feedback to the surgeon. Local injection of lidocaine with epinephrine is employed for the procedure (which may also be done under general anesthesia in order to minimize oozing); the injection may need to be repeated once deeper dissection is performed, so additional local anesthesia should be on the surgical field. Use of topical transtracheal anesthesia greatly facilitates the procedure by suppressing excessive coughing. In children, a Bjork flap should be avoided to minimize the tracheal incision. In general, a small incision should be made and stay sutures used instead. The size of the tracheostomy tube varies and is circumstance-dependent. In most cases, we utilize a #6 cuffed tube in adults.

PERCUTANEOUS TRACHEOSTOMY

Percutaneous technique for tracheostomy is an alternative for adults. The procedure should be performed by experienced practitioners using bronchoscopic guidance. The main contraindication for the procedure is severe clinical instability, when bronchoscopy is not tolerated. In patients with coagulopathy, open tracheostomy is usually favored. Morbid obesity is considered by many as a relative contraindication for percutaneous tracheostomy, as is suspicion of cervical spine instability. In such cases, concern about eventual accidental decannulation may lead the team to choose an open technique and a more secure airway, such as a Bjork flap or an "epithelial-lined" tracheostomy.

POSTTRACHEOSTOMY COMPLICATIONS AND MANAGEMENT

In a survey of the American Academy of Otolaryngology–Head and Neck Surgery, 478 members responded to inquiries regarding 4 specific complications of tracheostomy. In all, 66% of "catastrophic" events involved loss of airway or bleeding; 34% were specifically related to loss of the airway. Accidental decannulation occurred much more frequently than loss of airway during planned tracheostomy change (nearly 90% were the former). A total of 32% were related to major bleeding, and more than 90% of these were specified as tracheoinnominate fistulae (TIF). TIF was more common in the pediatric population. Fourteen percent of the events involved obstruction of the tube. Authors of the study reported a "very approximate" annual estimate of 1000 such events, with about half of these causing death or permanent morbidity. The overwhelming majority of events occurred more than 7 days following tracheostomy.

Other complications should be noted, although they are less frequently "catastrophic."[40] For example, pneumothorax is rare, but a postprocedure chest radiograph should be performed in all patients. Many airway occlusive events can be managed with suctioning, and such events are the most frequent cause of tracheostomy-related emergencies. In our experience, most bleeding events are self-limited. However, worth noting is the role of CT angiography based on the findings from a flexible fiberoptic examination. False passage and decannulation also occur, particular in obese patients; prevention is better than management. Esophageal injury (i.e., tracheoesophageal fistula) is a rare but catastrophic complication that should be considered in patients who have postoperative dysphagia or aspiration. Tracheostomy, itself, may promote aspiration by tethering the larynx or decreasing the cough reflex by limiting subglottic pressure, especially when associated with laryngeal injury, tracheal stenosis, or recurrent laryngeal nerve paralysis. Tracheocutaneous fistula is a long-term complication that can usually be avoided by using a meticulous decannulation technique: downsizing the tracheostomy tube, capping the tube, taping the tracheostomy stoma, and instructing the patient on tracheostomy tube occlusion during speech and coughing while the stoma is healing. When tracheocutaneous fistula is persistent, repair can usually be done with local tissue and, if possible, a staggered three-layer repair technique.

AEROSOL-GENERATING PROCEDURES AND CONTAGION

Experience with virus outbreaks such as MERS, SARS, and COVID-19 have demonstrated that aerosol-generating procedures (AGPs) carry a high risk of viral transmission to clinicians. Fiberoptic inspection of the airway, mask ventilation, intubation, and creation of a surgical airway all constitute AGPs.[41] Best practices with regard to AGP and virus transmission continue to evolve from the lessons learned during the COVID-19 global pandemic.[42] Important considerations include use of personal protective equipment, proper patient room ventilation (e.g., negative pressure), limitation of the number of staff in the room, communication strategies employed during emergencies, and efforts at minimization of potential aerosol dispersion that can occur during laryngoscopy, mask ventilation, or ventilator circuit disconnects.[42] Critically important is that clinicians have the opportunity to become familiar with new processes, protocols, and equipment through dress rehearsals and simulation. Of course, the best practice for a given environment will need to be tailored to local resources and experience.

CONCLUSIONS

Many considerations are important to effective upper airway management. The astute clinician has a foundational knowledge of upper airway anatomy, airway assessment rubrics to predict management difficulty, access to the latest technology to facilitate intubation, and a willingness to endorse a team approach to safety. Communication effectiveness is as crucial to safe airway management as are equipment readiness and technical skills. A rigorous approach to chart review and airway planning is also critical to success.

A range of effective approaches to upper airway management exists, and the expert will have sufficient familiarity and experience with each to allow for adaptation to the unique clinical circumstances of the patient. At times, airway consultants may be needed to provide unique skills and equipment in airway assessment, management, or rescue. These skills include familiarity with emergency front-of-neck access, as well as an ability to assess and rescue the patient with an in-situ tracheostomy or laryngectomy. A well-defined, systems-based approach to activate additional expertise and specialized equipment, when needed, is preferred to an ad-hoc system.

CHAPTER 146

Hemodynamic and Respiratory Monitoring in Acute Respiratory Failure

Hari M. Shankar
Brian J. Anderson

INTRODUCTION

Acute respiratory failure (ARF) accounts for a substantial portion of intensive care unit (ICU) admissions. Patients receiving invasive mechanical ventilation, as well as those receiving noninvasive respiratory support, such as high-flow nasal cannula and noninvasive positive-pressure ventilation, are at risk for hemodynamic and further respiratory decompensation. Therefore, close monitoring is necessary to identify early signs of instability and to allow for prompt intervention to prevent morbidity and mortality.

The primary goals of monitoring include ensuring adequate circulatory function, ensuring adequate ventilation and oxygenation, detecting the mechanisms of circulatory or respiratory decompensation when they occur, providing surveillance for common complications associated with noninvasive and invasive respiratory support, evaluating hemodynamic and respiratory responses to therapeutic interventions, and watching the trajectories of hemodynamic and respiratory disorders over time to gain insight into a patient's prognosis.

Given the myriad forms of physiologic monitoring available to the modern clinician, many considerations should be taken into account when deciding which monitoring parameter and system to use. First, clinicians should select parameters and systems that have proven accuracy for the specific patient and clinical scenario. Second, clinicians should take into consideration the level of comfort and expertise that the entire clinical team has with the chosen monitoring system. Even the most precise and advanced monitoring system can lead clinical teams astray if they lack the expertise to appropriately interpret and act upon the data it provides. Third, and most important, physiologic monitoring data should not be evaluated in isolation, as reliable interpretation of data necessitates review of multiple data sources in a collective fashion at a single time point, as well as review of trends in data over time.

This chapter reviews the various parameters and methods available for hemodynamic and respiratory monitoring in patients with ARF.

HEMODYNAMIC MONITORING

In this section, we review noninvasive and invasive methods for hemodynamic monitoring in patients with ARF. Respiratory monitoring is detailed in a subsequent section of this chapter.

Hemodynamic assessment is a vital component of caring for critically ill patients. In addition to alerting clinicians to early signs of hemodynamic decompensation, it can provide important diagnostic information on the cause of the patient's respiratory failure, including differentiation between cardiogenic and noncardiogenic pulmonary edema—a distinction that has clear therapeutic implications.

Hemodynamic monitoring is also vital in identifying untoward effects of positive-pressure ventilation on the cardiovascular system. Positive-pressure ventilation increases intrathoracic pressure, decreases venous return, and increases pulmonary vascular resistance, thereby potentially reducing right ventricular cardiac output and causing right ventricular dilatation. In certain patients, these effects can impair left ventricular filling if the impaired right ventricular function and cavity dilatation cause the interventricular septum to impinge on the left ventricle due to ventricular interdependence. Positive-pressure ventilation may lead to an overall summative reduction in cardiac output and, in rare circumstances, such as in patients with severe pre-existing right ventricular dysfunction or pulmonary hypertension, may lead to cardiovascular collapse.

Below we discuss electrocardiogram monitoring, noninvasive and invasive blood pressure monitoring, invasive central venous monitoring, cardiac and thoracic echocardiography, and novel cardiac output monitoring systems.

Electrocardiogram Monitoring

A continuous bedside electrocardiogram (ECG) is a common function of bedside monitors in the intensive care unit. The bedside ECG generally involves 3 to 5 leads, as opposed to the standard 12 leads, and provides a method for measuring heart rate and assessing heart rhythm.

Heart rate (HR) is, perhaps, the simplest hemodynamic parameter to monitor. However, despite its simplicity, its relationship to cardiac output mandates that it not be overlooked. Tachycardia is one of the earliest compensatory responses to volume depletion and can alert clinicians to hypovolemia well in advance of a change in blood pressure. Bradycardia may occur as a result of medications commonly used in patients with ARF, most notably propofol and dexmedetomidine; clinicians need to ensure an adequate cardiac output is maintained when patients develop bradycardia while these medications are administered. Similar assurance must be sought in patients with elevated HR, as tachycardia may impair cardiac filling and compromise cardiac output. Unfortunately, most bedside monitors do not display trends in HR. Therefore, clinicians should use electronic or bedside flow sheets to assess for changes in HR over time.

The continuous ECG also provides a method to monitor heart rhythm and can alert bedside clinicians to arrhythmias. Atrial fibrillation is the most common arrhythmia in critically ill patients, occurring in an estimated 10% to 40% of patients during their ICU stay.[1–4] Although most cases occur in patients with preexisting atrial fibrillation, approximately 5% to 25% of patients develop new onset of the arrhythmia as part of their critical illness.[1,2,4–6] Risk factors for new-onset atrial fibrillation include increased age, underlying cardiovascular disease, sepsis, shock, use of vasopressors or inotropes, severe illness, and heart failure.[2–7] Patients with new-onset atrial fibrillation have higher rates of renal replacement therapy (RRT) and mechanical ventilation, longer ICU and hospital lengths of stay, and higher mortality.[1,3–6,8] In critically ill patients with sepsis, new-onset atrial fibrillation has also been linked to a higher rate of in-hospital stroke and subsequent heart failure.[8,9]

Blood Pressure Monitoring

Blood pressure (BP) is a core hemodynamic parameter monitored in critically ill patients.

General Principles

Mean arterial pressure (MAP) is the most commonly used blood pressure variable in managing critically ill patients. A target MAP goal >60 to 65 mm Hg has historically been suggested and is recommended by societal guidelines.[10,11] Below this target, autoregulatory mechanisms that protect regional perfusion may fail, and blood flow becomes entirely dependent on pressure. Observational studies have similarly linked the amount of time spent below a MAP of 60 to 65 mm Hg with worse outcomes, including higher mortality and need for RRT.[12–15] However, arterial hypertension has been shown to shift the autoregulatory curve higher,[16] and some observational studies have suggested that higher MAP targets (75–85 mm Hg) are necessary to avoid kidney injury.[14,17] Prospective studies targeting higher MAP targets have been mixed.

Nonrandomized studies targeting a MAP of 75 to 85 mm Hg using higher doses of vasopressors demonstrated an increase in cardiac output and oxygen delivery but did not demonstrate improvements in tissue perfusion as measured by serum lactate, capillary blood flow, urinary output, or renal function.[18–20] More recently, two randomized controlled trials evaluated higher MAP goals (75–85 mm Hg) primarily in patients with septic shock.[21–23] Overall, there was no difference in mortality, and patients randomized to the higher MAP target had a greater rate of new-onset atrial fibrillation and a longer duration of vasopressor use; notably, they did not appear to have a longer ICU length of stay.[21–23] Interestingly, both studies and a subsequent patient-level pooled analysis revealed significant differences in specific subgroups. Among patients with chronic hypertension, the higher MAP target was associated with a lower risk of acute kidney injury and RRT.[21] Alternatively, mortality was higher in patients receiving vasopressors for >6 h prior to enrollment and in older patients randomized to the higher MAP target.[22,23]

Based on these data and consensus guidelines, an initial MAP of 65 mm Hg or higher should be targeted for most patients with ARF. Patients with chronic hypertension can be considered for a higher MAP goal, particularly if there is concern for concurrent renal injury. Although data are sparse, patients with cirrhosis with a baseline low MAP may achieve adequate perfusion at a lower MAP goal.[24]

Methods of Blood Pressure Measurement

Four methods for BP measurement are used primarily, including three intermittent, noninvasive methods and one invasive continuous method. Intermittent methods utilize an inflatable cuff and can be performed manually using the palpatory or auscultatory methods, or with an automated oscillometric device. Continuous BP measurement involves an intra-arterial catheter that provides beat-by-beat measurement as well as arterial blood sampling capabilities.

With the palpatory method, only a BP cuff with a sphygmomanometer is required. The cuff is inflated while the radial pulse is palpated, and when the pulse can no longer be palpated the cuff is slowly deflated until the pulse can again be palpated. The pressure at which the radial pulse returns corresponds to the systolic blood pressure (SBP). Despite providing only SBP, the palpatory method may be useful in emergencies when equipment is limited, or in noisy environments when the auscultatory method can be challenging.

For the auscultatory method, both a BP cuff with a sphygmomanometer and a stethoscope to detect the characteristic Korotkoff sounds are required. The cuff is inflated above the anticipated SBP, confirmed by an inability to palpate the radial pulse, and the stethoscope is placed distal to the cuff on the upper arm over the brachial artery while the cuff is slowly deflated. The onset of Korotkoff sounds corresponds to the SBP and the disappearance of the sounds corresponds to the diastolic blood pressure (DBP). The auscultatory method is preferred over the palpatory method, given that it provides both systolic and diastolic pressures and thus provides the possibility of calculating the MAP using the formula:

$$MAP = (1/3 \times SBP) + (2/3 \times DBP)$$

Although manual BP measurement is still used in clinical practice, automated BP measurement has become the norm due to the frequency of measurement required in critically ill patients and the widespread availability of oscillometric devices. Similar to the manual methods, oscillometric devices utilize a cuff that is inflated until it exceeds the SBP and is then slowly deflated while sensing the return of blood flow. These devices detect oscillations that occur with the return of flow, and the maximum amplitude of these oscillations corresponds to the MAP.[25] SBP and DBP are subsequently calculated using algorithms that are generally proprietary for each device.[25] Oscillometric devices are time-saving, and in most circumstances, provide an accurate and reproducible measurement of MAP. Although uncommon, excessively frequent measurements using an automated device may lead to complications, including bruising, petechiae, pain, limb edema, or peripheral neuropathy.

BP measurement using an intra-arterial catheter (commonly referred to as an "arterial line" or "a-line") is considered the gold standard for determining arterial blood pressure. The radial artery is the most common site for catheter placement, followed by the femoral artery. Less common sites include the brachial, ulnar, and dorsalis pedis arteries. Once inserted, the arterial catheter is connected to fluid filled tubing, which is connected to a pressure transducer that converts pressure changes in the tubing into an electrical signal from which a pressure waveform is generated. Arterial lines provide direct measurement of SBP and DBP, whereas MAP is calculated by integrating the area under the pressure waveform during a single beat and is usually averaged over a specific time period.

Indications for continuous invasive BP monitoring include difficulty with obtaining accurate noninvasive measurements; shock or need for titration of vasopressor medications, especially when patients do not respond to initial therapy; and a requirement for frequent laboratory testing, including frequent arterial blood gas sampling. Although invasive BP monitoring was shown to increase detection of hypotension and resulted in more frequent intervention for hypotension in one intraoperative study, a paucity of data exists linking invasive BP monitoring with clinical outcomes. In addition, arterial lines are not without risk.[26]

Common complications of arterial lines include pain, swelling, bruising, hematoma formation, and minor bleeding. Thrombosis is uncommon in the femoral artery, but relatively common in peripheral arteries, with nonocclusive thrombosis occurring in up to 60% of radial arterial lines and occlusive thrombosis in 15% to 30% of radial arterial lines.[27–30] Although usually not clinically significant, thrombosis can lead to limb ischemia in rare cases. Risk factors for thrombosis include arterial spasm at the time of catheterization, larger catheters, smaller vessels, peripheral vascular disease, and longer duration of arterial cannulation.[27–29,31–33] The rate of arterial catheter-related blood stream infection has been reported to range from 1.0 to 1.7 per 1000 catheter-days, a rate that is similar to antimicrobial-coated short-term central venous catheters commonly used in critically ill patients.[34–36] Higher infection rates have historically been reported with femoral artery catheters, although recent studies have shown higher rates of colonization but not infection, suggesting that modern infection-prevention practices may have improved infection rates for femoral arterial lines.[35,37,38] Rare but severe complications of arterial lines include air embolism, pseudoaneurysm, arteriovenous fistula formation, and retroperitoneal hemorrhage (with femoral site cannulation).

Accuracy of Blood Pressure Measurement Methods

The two most common methods for BP measurement in critically ill patients, oscillometric and intra-arterial, are both prone to measurement error that may have a clinically significant impact.

The most common source of error with oscillometric BP measurement is an inappropriate cuff size. Cuffs that are too large will produce falsely low oscillometric readings and thus underestimate the MAP, whereas cuffs that are too small will produce falsely high readings and overestimate MAP. Oscillometric measurement can also be impacted by a shivering patient, arrhythmias, or severe hypotension. The accuracy of oscillometric BP measurements when measured at sites other than the upper arm is poor in critically ill patients and should be interpreted with caution.[39]

For intra-arterial BP measurement, improper leveling of the transducer may introduce error, and clinicians must ensure the catheter has been correctly "zeroed" before interpreting values. Assessment of the quality of the arterial waveform is also critical prior to interpreting values. The two main artifacts that can alter the arterial wave form are underdamping and overdamping (Fig. 146-1).[40] With underdamping, the arterial waveform overestimates SBP, underestimates DBP, and overestimates pulse pressure (PP). Causes of underdamping include overly stiff tubing, excessive tubing length, tubing connected with multiple stopcocks, or a defective transducer. Alternatively, overdamping results in underestimation of SBP, overestimation of DBP, and underestimation of PP. Overdamping can occur due to air bubbles or clots in the tubing, loose connections, kinked tubing, and low pressure in the infusion bag. The degree of damping can be assessed using the *fast-flush test* and calculating the damping coefficient, although in clinical practice the fast-flush test is usually simply inspected visually. Normally, with a "snap" flush of the arterial line, a square wave tracing is generated, followed by a single oscillatory wave; more than one oscillation indicates underdamping, while the absence of any oscillations indicates overdamping. Underdamping is the most common in clinical practice, occurring in up to 30% of patients, and is particularly common in patients with hypertension or chronic obstructive pulmonary disease.[41]

Figure 146-1 Arterial waveforms and flush test for a normal arterial waveform *(middle)*, underdamped arterial waveform *(top)*, and overdamped arterial waveform *(bottom)*. Underdamping may be suggested by a deep dicrotic notch or nonphysiologic oscillations in the diastolic runoff phase. Underdamped waveforms overestimate systolic blood pressure, underestimate diastolic blood pressure, and overestimate pulse pressure. Overdamping may be suggested by a slurred systolic upstroke and absence of the dicrotic notch. Overdamped arterial waveforms underestimate systolic blood pressure, overestimate diastolic blood pressure, and underestimate pulse pressure. *(Reproduced with permission from Saugel B, Kouz K, Meidert AS, et al. How to measure blood pressure using an arterial catheter: a systematic 5-step approach. Crit Care. 2020;24(1):172.)*

In general, when performed correctly, MAP correlates well between oscillometric and intra-arterial measurements across a relatively wide range of pressures. However, oscillometric devices tend to overestimate SBP at low values and underestimate SBP at high values when compared to intra-arterial measurement,[42–47] and the difference may be greater than 10 mm Hg up to 50% of the time.[43] Importantly, the overestimation of SBP is more pronounced in hypotensive patients and in patients receiving vasopressors, which may falsely reassure clinicians.[42,43,45] Lastly, small studies have suggested that oscillometric devices may significantly underestimate both MAP and SBP in obese patients.[47,48]

In summary, routine noninvasive monitoring of MAP using an oscillometric device is appropriate for most hemodynamically stable patients, and invasive BP monitoring should be considered in patients with severe hypotension or severe hypertension; in patients receiving vasopressors, especially if they are not responding to initial therapy; and in obese patients.

■ Invasive Central Venous Monitoring

Central venous catheters (CVCs) are frequently inserted in critically ill patients, particularly in patients with concurrent shock. CVCs are used for vasopressor infusion, central venous pressure measurement, and measurement of central venous oxygen saturation. In select circumstances, pulmonary artery catheters may be used to measure mixed venous oxygen saturation, pulmonary artery pressures, and pulmonary occlusion (wedge) pressure.

Central Venous Pressure

Central venous pressure (CVP) represents the blood pressure in the vena cava and is a good approximation of right atrial pressure; hence, it can be used to estimate right ventricular preload. CVP can be measured by connecting one of the CVC lumens to a pressure transducer and, similar to arterial lines, the transducer must be appropriately leveled and zeroed. Clinicians must also have experience interpreting the CVP waveform, as CVP should generally be measured at the base of the *c* wave at end-expiration (Fig. 146-2).

In patients with shock, CVP may be helpful in differentiating the underlying pathophysiology. Distributive and hypovolemic shock may be associated with a low CVP, whereas obstructive shock may be associated with a high CVP. However, these are generalizations, and clinicians need to interpret the CVP in the broad context of the patient's presentation. The CVP waveform may also be useful for identifying specific cardiac disorders. A large *v* wave is suggestive of tricuspid regurgitation and may be seen in patients with right ventricular failure. An attenuated *y* wave descent may be seen in cardiac tamponade, whereas a prominent *y* wave descent may be seen in pericardial restriction or right ventricular overload.

CVP has historically been used to guide fluid resuscitation; however, numerous studies have demonstrated that CVP is a poor marker of fluid responsiveness, and consensus guidelines recommend against using static measures like CVP to assess the likelihood of fluid responsiveness, favoring use of dynamic variables.[10,11] Although CVP can be elevated in patients with left ventricular failure and pulmonary edema, ARF and positive-pressure ventilation (and, especially, positive end-expiratory pressure) may increase pulmonary vascular resistance and impair right ventricular function,

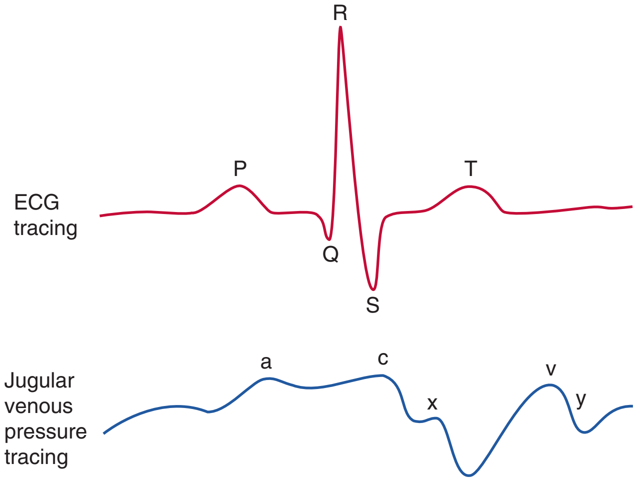

Figure 146-2 CVP waveforms. Since there are no valves between the vena cava and the right atrium, central venous pressure waveform reflects the events of cardiac contraction. Simultaneous display of the ECG allows one to identify and time the CVP waveform. **a wave.** Increased atrial pressure during right atrial contraction. It occurs following the P wave on an ECG. **c wave.** During early ventricular contraction the tricuspid valve bulges into the right atrium. It occurs at the end of the QRS segment on an ECG. **x descent.** Atrial relaxation. It occurs before the T wave on an ECG. **v wave.** Atrial filling—the right atrium progressively fills while the tricuspid valve is closed. It occurs at the end of the T wave on an EKG. **y descent.** Following opening of the tricuspid valve in diastole, the atrium empties as blood flows into the right ventricle. It occurs before the P wave on an ECG.

resulting in a high CVP and making CVP by itself insufficient to differentiate cardiogenic from noncardiogenic pulmonary edema.

Venous Oxygen Saturation

Shock is defined as global tissue hypoxia and occurs as a result of an imbalance between oxygen delivery and oxygen demand. Under normal physiologic conditions, oxygen demand and oxygen delivery are well matched. When oxygen demand increases, the higher demand is first mitigated by an increase in cardiac output. When the oxygen demand cannot be met by an increase in cardiac output, an increase in oxygen extraction occurs at the tissue level. Once these compensatory mechanisms are overwhelmed, shock and anaerobic metabolism ensues.

Because most of blood oxygen is bound to hemoglobin, the oxygen saturation of blood returning to the lungs provides a surrogate measure for the adequacy of global oxygen delivery. The oxygen saturation of blood in the pulmonary artery is referred to as the mixed venous oxygen saturation (Sv_{O_2}) and, under normal circumstances, ranges from 65% to 75%. Lower Sv_{O_2} values, particularly values below 50%, suggest inadequate oxygen delivery compared to oxygen demand (i.e., shock). High Sv_{O_2} values can be seen in patients with poor oxygen extraction, including patients with septic shock, or in high cardiac output states.

In addition to providing an assessment of global oxygen adequacy, Sv_{O_2} can be used to estimate cardiac output and cardiac index, using the Fick equation:

$$CO = V_{O_2}/(Ca_{O_2} - Cv_{O_2})$$

where CO is cardiac output, V_{O_2} is oxygen consumption, Ca_{O_2} is arterial oxygen content and Cv_{O_2} is venous oxygen content. Oxygen content is calculated as:

$$C_{O_2} = (1.34 \times [Hgb] \times \%\ Hgb\ saturation) + 0.003 \times P_{O_2}$$

where $[Hgb]$ is the hemoglobin concentration and P_{O_2} is the partial pressure of oxygen. Once calculated, cardiac index can be calculated using the formula:

$$CI = CO/BSA$$

where BSA is the patient's body surface area.

In general, monitoring Sv_{O_2} is superior to monitoring cardiac output because inadequate oxygen delivery can occur despite a normal or elevated cardiac output. A major barrier to Sv_{O_2} monitoring is that it requires use of a pulmonary artery catheter—a device that has fallen out of favor and is generally reserved for select circumstances, as discussed in the next section. Fortunately, the central venous oxygen saturation (Scv_{O_2}) can often be used as a surrogate for Sv_{O_2} and can be easily measured using a routine CVC in both ICU and non-ICU environments.

Scv_{O_2} measured from the superior vena cava (SVC) has been shown to strongly correlate with Sv_{O_2}, but, on average, is approximately 2% to 8% higher than Sv_{O_2}, thus slightly overestimating global oxygen adequacy.[49–60] Although the Sv_{O_2} – Scv_{O_2} difference is less than 10% in most patients, it can be greater than 10% in up to 30% of patients, with differences as high as 15% to 20% in some cases.[49,55–57,60] A normal Scv_{O_2} (≥70%) is almost always reassuring, with a negative predictive value for a low Sv_{O_2} of 94% to 96%.[51,56] An important limitation of using the SVC Scv_{O_2} is that the Scv_{O_2} – Sv_{O_2} difference may be greater at lower Sv_{O_2} levels when accuracy is most relevant, in patients with hypocapnia, and in patients with elevated intracranial pressure.[55,57,59,61,62] Venous oxygen saturation measured in the right atrium, sometimes denoted Sra_{O_2}, is generally more accurate and has been reported to differ from Sv_{O_2} by only 1% to 3% on average.[49,52,53,58,62]

Pulmonary Artery Catheterization

Historically, pulmonary artery catheters (PACs) were inserted routinely for hemodynamic monitoring in critically ill patients and patients undergoing high-risk surgery.[63] The PAC can provide direct measurements of CVP, right atrial pressure, right ventricular pressure, pulmonary artery pressure, and pulmonary capillary occlusion pressure (PAOP, also referred to as the pulmonary capillary wedge pressure [PCWP]). PACs can also be used to measure cardiac output and mixed venous oxygen saturation, as well as to determine systemic and pulmonary vascular resistances, which can be helpful in differentiating types of shock.

Over the past 20 to 30 years, the use of PACs has become far less common due to higher rates of complications compared with CVCs and numerous clinical trials that failed to demonstrate a clear improvement in outcomes among patients managed with PACs.[64–71] Currently, PACs are mostly reserved for patients with unexplained shock, refractory cardiogenic shock, decompensated pulmonary hypertension, and select patients undergoing high-risk surgery.

When performed, pressures obtained from a PAC may be helpful in differentiating the cause of a patient's respiratory failure if not determined through other means. Elevated right-sided pressures are seen in patients with pulmonary embolism, acute respiratory distress syndrome (ARDS) as a result of hypoxic vasoconstriction, chronic pulmonary hypertension, hypervolemia, and left-sided heart failure. In patients for whom cardiogenic versus noncardiogenic pulmonary edema is being considered, the pulmonary capillary occlusion pressure may be helpful as an estimate of the left atrial pressure, with higher values (>15 to 18 mm Hg) generally suggestive of hydrostatic pulmonary edema.

■ Ultrasonography

Ultrasonography is an essential tool for hemodynamic assessment in patients with respiratory failure and, particularly, patients with concurrent shock. In addition to formal echocardiography, focused bedside cardiac and thoracic ultrasound is increasingly recognized as a valuable tool due to its widespread availability and increasing experience among clinicians. Both echocardiography and thoracic ultrasound can provide diagnostic information to help categorize shock and respiratory failure and can be used to assess for complications of therapy.

Echocardiography

Transthoracic echocardiography (TTE) is generally rapidly available, reliable, provides adequate images for the vast majority of critically ill patients, and is highly sensitive and specific for cardiac causes of shock.[72] A transesophageal echocardiogram (TEE) is generally reserved for patients in whom TTE images were inadequate for the diagnostic question at hand, such as evaluation for atrial thrombus or endocarditis.

Basic critical care echocardiography involves a limited number of standard echocardiographic views, including the parasternal long axis, parasternal short axis, apical four chamber, and subcostal long axis. Although useful as a standalone tool, focused critical care echocardiography does not eliminate the need for standard echocardiography, especially in patients in whom image quality is poor, when confirmation of a diagnosis is required, or when significant valvular disease is under consideration. Common indications for echocardiography in patients with ARF include assessment of left ventricular (LV) function, assessment of right ventricular (RV) function, assessment of fluid status, and evaluation for right-to-left shunting.

LV function and LV size are commonly measured or qualitatively evaluated as part of an echocardiogram. LV systolic and diastolic dysfunction can be seen in patients with ARF due to decompensated left-sided heart failure, and LV systolic dysfunction can also be seen as a result of ischemia, as well as sepsis- or stress-induced cardiomyopathy. Thus, echocardiography can be useful in differentiating the cause of ARF, as well as in assessment for cardiac complications of common forms of critical illness.

RV dysfunction is common in critically ill patients, especially in patients with pulmonary embolism or ARDS.[73] Importantly, RV dysfunction can also be caused by excessive mean airway pressure, as seen in patients treated with high PEEP. In addition to assessing RV function, echocardiography can assess RV dilation and tricuspid regurgitation, which are additional signs of RV overload. Early recognition of RV failure is paramount in critically ill patients, as overresuscitation of a failing RV can lead to further hemodynamic deterioration.

New-onset right-to-left shunting is common in critically ill patients due to the relatively high prevalence of patent foramen ovale in the general population (25% to 30%) and the frequent occurrence of RV dysfunction in critical illness that can ultimately increase right atrial pressure to the point it exceeds left atrial pressure.[74,75] Shunting should be suspected in patients with hypoxemia out of proportion to imaging findings, when hypoxemia fails to respond to higher $\mathrm{Fi}_{\mathrm{O}_2}$, and when hypoxemia fails to improve or worsens with increased PEEP. A right-to-left shunt can be detected by injecting agitated saline through a peripheral or central vein during echocardiography and is commonly referred to as a "bubble study." The appearance of microbubbles in the left atrium within the first three cycles is seen in intracardiac right-to-left shunts, whereas the presence of microbubbles in later cycles is seen in intrapulmonary shunts.

Echocardiography may also be helpful in estimating volume status. The inferior vena cava expiratory diameter and the *inferior vena cava collapsibility index* have been studied as tools to determine fluid responsiveness, as well as to identify patients with heart failure.[76–78] In spontaneously breathing patients, the IVC collapsibility index is calculated as maximum IVC diameter on expiration − (minimum diameter on inspiration/maximum diameter on expiration); in mechanically ventilated patients, the index is known as the *IVC distensibility index* and is calculated as (IVC maximum diameter on inspiration − minimum diameter on expiration)/minimum diameter on expiration. Although studies have shown consistent differences in these metrics according to volume responsiveness and presence of heart failure, specific cut-points of each metric have been shown to be only moderately predictive.[76–78] Therefore, they should not be used in isolation but may be valuable as part of a comprehensive assessment of volume status.

Thoracic Ultrasound

Thoracic ultrasonography is a powerful tool in patients with ARF and can be used to diagnose pulmonary edema, pleural effusions, and pneumothorax. Importantly, simple systematic approaches are available to ensure a thorough examination, and interpretation of thoracic ultrasound requires knowledge of only a handful of characteristic findings.[79,80]

Ribs can be identified as round, hyperechoic structures with distal acoustic shadowing. Just below the rib line, the *pleural line* can be identified as a hyperechoic and sliding, or shimmering, line that represents the movement of the visceral pleura against the parietal pleura during the respiratory cycle. Below the pleural line, *A lines* can be identified as motionless horizontal lines spaced at regular intervals from the pleural line and represent reverberation artifacts created by the ultrasound beam and the pleural line. The presence of a normal sliding pleural line (often referred to as "*lung sliding*") and A lines represent the normal lung pattern.

B lines or "comet tails" are vertical artifacts that arise from the pleural line and extend the entire depth of the ultrasound beam, interrupting A lines that may be present. B lines are reverberating artifacts resulting from interlobular septal thickening and alveolar fluid and represent the so-called alveolar-interstitial syndrome.[81] A small number (<3) of B lines in any given zone of the lung is considered normal. B lines are not specific to alveolar edema and may result from other processes that thicken the interstitium or cause interstitial inflammation, such as lung fibrosis or pneumonitis. B lines that are 7 mm or more apart are caused by interlobular septal thickening characteristic of interstitial edema, whereas B lines ≤3 mm apart are caused by alveolar edema. With additional findings, lung ultrasound may help differentiate cardiogenic from noncardiogenic pulmonary edema (i.e., ARDS). Focal B lines with a nonhomogenous distribution with spared areas, subpleural consolidations, an irregular pleural line, and reduced pleural motion are characteristic findings in ARDS.[82] Alternatively, diffuse bilateral B lines in a homogenous distribution and a smooth pleural line are characteristic of cardiogenic pulmonary edema.[82]

Thoracic ultrasound can also be used to assess for pneumothorax, which can occur as the result of common procedures in critically ill patients, such as thoracentesis, CVC insertion, and barotrauma from positive-pressure ventilation. Because a pneumothorax can rapidly progress and cause tension physiology, thoracic ultrasound for rapid diagnosis of a pneumothorax should be considered in patients who develop hemodynamic instability in relation to these procedures. When evaluating for a pneumothorax, multiple adjacent rib spaces should be evaluated in a short period of time. The presence of lung sliding or B lines are definitive findings that exclude pneumothorax, but notably, *only at that particular rib space*, highlighting the importance of scanning multiple rib spaces to fully evaluate the thorax. A pneumothorax is suggested by the absence of a lung sliding; however, the absence of lung sliding is not diagnostic and can be seen in conditions that eliminate movement between the visceral and parietal pleura, such as malignant processes, parapneumonic processes, or prior pleurodesis. Alternatively, the presence of a *lung point*, an intermittent respirophasic appearance of lung sliding that represents the boundary between the pneumothorax and an area of lung that still has apposition of the two parietal surfaces, is diagnostic of a pneumothorax.

The reader is referred to Chapter 29 for additional discussion of thoracic ultrasound.

Novel Hemodynamic Monitoring Tools

In most patients with ARF, the history, physical examination, laboratory testing, bedside ultrasonography, and basic bedside monitoring are adequate for hemodynamic monitoring and to diagnose causes of hemodynamic decompensation. In patients with unclassified shock or in patients who don't respond to initial therapy, the addition of cardiac output monitoring may be helpful. Although measurement of cardiac output from a PAC using thermodilution is considered the gold standard, the inherent issues with PACs have led to the development of numerous, less invasive methods for monitoring cardiac output. Although potentially useful in a variety of settings, data from randomized trials are insufficient to support their routine use.

Arterial Pulse Contour Analysis

Arterial pulse contour analysis or arterial pulse wave analysis relies on the relationship of the arterial pressure waveform to stroke volume and the elastic properties of the arterial wall. The area under the arterial waveform is reflective of stroke volume and, therefore, along with heart rate can be used to estimate cardiac output. To account for the elastic properties of the arterial wall, calibration of the pressure signal with an alternative method for measuring cardiac output or algorithms using preexisting patient data is required.

The PiCCO system (Getinge, Sweden) is based on pulse contour analysis of the systolic portion of the arterial waveform and is calibrated using transpulmonary thermodilution, in which a cold bolus of saline is injected into a central vein and changes in blood temperature are measured at a thermistor in an arterial catheter. For the PiCCO system, both a CVC and a separate arterial catheter (usually femoral) are required.

LiDCOplus (LiDCO, England) is similar to PiCCO except that it is based on pulse power analysis of the entire arterial waveform and is calibrated using lithium dilution instead of thermodilution. Benefits of LiDCO include its ability to be used with a radial arterial catheter and that its calibration does not require a CVC. Although calibrated pulse contour devices show good agreement with PAC thermodilution, frequent recalibration is necessary, particularly with changes in clinical status.[83,84]

Flotrac (Edwards Lifesciences, United States) uses pulse contour analysis, along with a proprietary algorithm built from demographic data (age, gender, height, etc.) from an expansive patient database to estimate cardiac output. The accuracy of uncalibrated devices has been challenged, especially in patients with shock. Further study is needed, given continued improvement in the technology.[83,84]

Esophageal Doppler

Esophageal doppler technology takes advantage of the proximity of the esophagus to the descending aorta. Insertion of a doppler probe allows for measurement of blood flow velocity in the aorta, which can then be used to estimate cardiac output. These calculations must take into account the diameter of the aorta, which in most cases is estimated from demographic data, rather than measured, and which may not be static in patients with shock undergoing resuscitation. Widespread use in critically ill patients is limited by the need to frequently reposition the probe and the limitation that it can be used only in deeply sedated patients.

Bioimpedance and Bioreactance

Bioimpedance uses the principle of electrical impedance (opposition to flow of electrical current) to estimate cardiac output. Blood is conductive of electricity and, therefore, changes in the blood content of the thorax that occur with cardiac contraction result in small changes in impedance that can be extrapolated to stroke volume and cardiac output. Bioreactance, the technology upon which the Starling system (Baxter, United States) is based, uses a related concept termed the "phase shift." These devices apply a low-frequency, high-amplitude electrical current that transverses the thorax and is recorded by other electrodes. The time delay between the application and measurement is the phase shift and is related to the amount of pulsatile blood flow in the thorax, allowing it to be used to estimate cardiac output. Studies on the accuracy of bioreactance-measured cardiac output have yielded inconsistent results, particularly in critically ill patients; their use is not widespread.[83,84]

RESPIRATORY MONITORING

Monitoring the respiratory system is a fundamental part of caring for patients with ARF. Regardless of the form of respiratory support, clinicians need to that ensure patients have adequate oxygenation and ventilation and must remain vigilant for respiratory decompensations that can occur as a result of acute events, such as mucus plugging, sepsis, pneumothorax, or new thromboembolic disease. Trending respiratory mechanics is also a critical component of respiratory monitoring and is used to minimize ventilator-induced lung injury, providing valuable prognostic information.

Specific topics discussed in this section focus on monitoring of oxygenation, ventilation, respiratory mechanics, ventilator waveforms, and respiratory muscle strength.

Oxygenation

Below we consider use of pulse oximetry, arterial and venous blood gases, and calculation of $\mathrm{Pa_{O_2}/Fi_{O_2}}$ and $\mathrm{Sp_{O_2}/Fi_{O_2}}$ ratios.

Pulse Oximetry

Oxygenation is routinely measured in hospital wards and ICUs using pulse oximeters. Pulse oximetry measures blood oxygen saturation by illuminating the skin with two wavelengths of light: 660 nm (red) and 940 nm (infrared). By measuring the ratio of absorbance at these wavelengths by oxygenated (oxyhemoglobin) and deoxygenated (deoxyhemoglobin) hemoglobin, the device generates an oxygen saturation and waveform. Routine pulse oximetry has proved advantageous in the acute care setting, even though studies have not demonstrated differences in clinical outcomes.[85]

Major advantages of pulse oximetry include its speed, noninvasive nature, limited adverse effects, and capacity to provide continuous data. However, the technique does have certain limitations.

In critically ill patients, the accuracy of measurements of pulse oximetry oxygen saturation ($\mathrm{SP_{O_2}}$) when compared with co-oximetry oxygen saturation ($\mathrm{Sa_{O_2}}$) as a reference standard is greatest at high oxyhemoglobin saturations.[86] When $\mathrm{Sa_{O_2}}$ is greater than 90%, the average difference between $\mathrm{Sa_{O_2}}$ and $\mathrm{Sp_{O_2}}$ is less than 2%; however, that difference increases when $\mathrm{Sa_{O_2}}$ drops below 90%, thus making pulse oximetry less reliable in hypoxemic states.[87]

Concerns have recently arisen regarding the accuracy of pulse oximetry in Black patients. A number of studies have reported that $\mathrm{Sp_{O_2}}$ frequently overestimates $\mathrm{Sa_{O_2}}$ in Black patients, potentially resulting in occult or unrecognized hypoxemia.[88,89] One study revealed that in patients with an $\mathrm{Sp_{O_2}}$ of 92% to 96%, occult hypoxemia ($\mathrm{Sa_{O_2}} < 88\%$) was three times more frequent in Black patients compared with white patients.[89] While further study is needed, it is clear that racial differences in pulse oximetry need to be recognized and incorporated into clinical care.

Since pulse oximetry does not measure $\mathrm{Pa_{O_2}}$ (arterial oxygen tension), large falls in $\mathrm{Pa_{O_2}}$ may go undetected until it reaches 60 to 70 mm Hg, the steep portion of the oxyhemoglobin dissociation curve.[90]

Pulse oximeters are also unable to account for measurement error in the presence of dyshemoglobins, such as methemoglobin, carboxyhemoglobin, or sulfhemoglobin. Thus, co-oximetry is necessary in situations where clinical suspicion for a dyshemoglobinemia is suspected.

Additional sources of potential error include hypotension, hypothermia, vasoconstriction, patient movement, and venous congestion (such as that due to tricuspid regurgitation).[91]

Arterial Blood Gas

Arterial blood gas (ABG) measurement is commonly performed in acutely ill patients to measure Pa_{O_2}, P_{CO_2}, pH, Sa_{O_2}, serum bicarbonate, and other variables, such as dyshemoglobins and electrolytes—information that is crucial to the management of critically ill patients.[92] ABG analysis is also used to accurately assess arterial oxygenation, by calculating the alveolar–arterial oxygen gradient or the Pa_{O_2}/Fi_{O_2} (P/F) ratio, both of which are essential to the management of patients with hypoxemic respiratory failure.[93]

Venous Blood Gas

Venous blood gas (VBG) analysis has become widespread and can be useful for respiratory monitoring in critical care settings. VBGs are easier and less painful to obtain than ABGs and can provide important information, including venous pH, P_{CO_2}, bicarbonate, and other data that may aid in the management of critically ill patients.[94] Many studies have focused on the generally good correlation between ABGs and VBGs in specific disease processes, such as diabetic ketoacidosis,[95] or in specific settings such as the emergency department.[96,97] A study done in ICU patients found excellent agreement between central VBGs and simultaneous ABGs for the detection of acid–base disorders, including in patients in shock.[98]

Pa_{O_2}/Fi_{O_2} and Sp_{O_2}/Fi_{O_2}

The Pa_{O_2}/Fi_{O_2} (P/F) ratio is a diagnostic criterion, as well as a criterion for stratifying the severity of ARDS. A P/F >200 but <300 mm Hg denotes mild ARDS; a P/F >100 but <200 mm Hg denotes moderate ARDS; and a P/F <100 mm Hg denotes severe ARDS.[93,99] However, the need for an arterial blood gas to calculate the P/F ratio can limit the diagnosis of ARDS in situations when the test is not readily available. Consequently, several studies have examined the potential role of the Sp_{O_2}/Fi_{O_2} (S/F) ratio as a surrogate for the P/F ratio. A 2007 analysis of ARDSnet data showed that the S/F ratio strongly correlated with a simultaneously drawn P/F ratio, and that an S/F ratio of 315 corresponded to P/F ratios of 300, the diagnostic cutoff for ARDS.[100] A more recent analysis investigated the use of a nonlinear imputation method to estimate the P/F ratio from the S/F ratio and found that the nonlinear method had reasonable accuracy among mechanically ventilated patients, particularly when Sp_{O_2} was $\leq 96\%$.[101]

■ Ventilation

Assessment of CO_2 metabolism requires knowledge of the concentrations of CO_2 present in plasma (PC_{O_2}) and in exhaled tidal volume (P_{ECO_2}), as well as the amount of CO_2 in the extracellular compartment (total CO_2 or bicarbonate concentration). These measurements can be used to determine the amount of dead space ventilation, diagnose acid–base disturbances, assess the adequacy of ventilation, and help confirm correct endotracheal tube (ETT) or tracheostomy tube placement. Values of CO_2 from these different compartments are commonly measured using blood gas analysis, capnography, or transcutaneous devices.

Dead Space Fraction

Understanding the fraction of dead space ventilation is important in gauging the severity of underlying lung disease in ARF. Dead space ventilation, which is made up of the sum of anatomic and physiologic dead space, is defined as the fraction of tidal volume that does not participate in gas exchange. The modified Bohr equation allows calculation of the dead space to tidal volume (V_D/V_T) ratio using the formula:

$$V_D/V_T = (Pa_{CO_2} - P_{ECO_2})/Pa_{CO_2}$$

where Pa_{CO_2} is the arterial partial pressure of CO_2 and P_{ECO_2} is the mean expired partial pressure of CO_2. The latter can be measured using a metabolic monitor that collects expired gas or using capnography in mechanically ventilated patients.[102]

End-tidal CO_2

Under normal physiologic conditions, alveolar P_{CO_2} is the same as Pa_{CO_2} and can be estimated by measuring end-tidal CO_2 (P_{ETCO_2}). However, this relationship does not hold true in states with significant physiologic dead space, such as ARF, pulmonary embolism, pulmonary vascular disease, or low cardiac output states, during which P_{ETCO_2} may underestimate Pa_{CO_2}. Even with this limitation, evidence exists to support the use of P_{ETCO_2} in cardiac arrest, as a measure of cardiopulmonary resuscitation (CPR) quality, to identify return of spontaneous circulation (ROSC), and to help guide prognosis.[103] There has also been interest in using capnography to predict fluid responsiveness and measure changes in cardiac output.[104] Although there has been significant interest in using capnography as an alternative to ABG analysis, P_{ETCO_2} correlates poorly with Pa_{CO_2} in critical illness due to the number of factors that impact P_{ETCO_2}, including ventilator settings, underlying lung disease, and cardiac output.[102]

Transcutaneous CO_2 Monitoring

Transcutaneous CO_2 (TC_{CO_2}) monitoring technology was first developed in the 1980s and is based on the understanding that CO_2 diffuses easily throughout the body. CO_2 can be measured indirectly by determining changes in the pH of an electrolyte solution applied to a heated skin sensor, usually placed on the earlobe or forehead. Conceptually, TC_{CO_2} monitoring can be used to measure arterial P_{CO_2} in respiratory failure and to estimate tissue perfusion in shock states. Although TC_{CO_2} monitoring is considered valid in routine respiratory care, its validity in critically ill patients has been challenged because poor perfusion, peripheral vascular disease, or vasopressors may confound measurements.[105] Technology has improved in recent years with better accuracy in critically ill patients, including patients with very high P_{CO_2} and patients on vasopressors;[106,107] however, lingering uncertainties about its accuracy have led to inconsistent and patchy use.

Endotracheal Tube Positioning and Cuff Monitoring

Verification of ETT placement is of vital importance. Misplacement of the ETT is common, particularly accidental intubation of the esophagus or the right mainstem bronchus. ETT placement can be confirmed in several ways, including auscultation of bilateral breath sounds, palpation of the ETT cuff in the jugular notch, fiberoptic bronchoscopy, chest radiography, and by determining the presence of P_{ETCO_2} using capnography or capnometry.[108]

The ETT cuff is an important component of the ETT that requires diligent and frequent monitoring. The inflated cuff functions to create a seal between the outer surface of ETT and the tracheal wall, permitting delivery of the tidal volume and preventing aspiration of nasopharyngeal secretions. Regular monitoring of the cuff is required to ensure that the pressure inside the cuff is kept below 20 to 25 cm H_2O, as the capillary perfusion pressure of the tracheal mucosa is approximately 25 cm H_2O and cuff pressures above this may lead to mucosal injury, ischemia, and eventually, tracheal stenosis or malacia.[108]

Following intubation and positioning of the ETT, the cuff balloon should be progressively inflated just until the gas leak that occurs during ventilation ceases. Measurement of cuff pressure requires connection of a manometer to the tubing leading to the cuff's pilot balloon. Excessively high cuff pressures may indicate either an undersized ETT for the patient's tracheal size or tracheal stenosis. Alternately, low cuff pressures, in addition to other signs such as audible noise during inspiration, frothy oral secretions with each breath, discrepancies between set and exhaled tidal volumes, and hypoxemia may suggest a cuff leak. Identification of a leak from the cuff mandates replacement of the endotracheal tube.[109]

■ Respiratory Mechanics

Characterization of respiratory system mechanics is fundamental to understanding the physiology of mechanically ventilated patients. Vital information can be gleaned, including respiratory system compliance, airway resistance, and the presence of restrictive or obstructive lung disease. Respiratory mechanics can also be helpful in identifying the etiology of episodes of clinical instability and monitoring the response to therapeutic interventions, such as diuresis or ventilator changes. Trending respiratory mechanics is also important to minimize ventilator-induced lung injury. Measurements should ideally be taken when the patient is passive with the ventilator, such as immediately after intubation or while otherwise sedated or paralyzed.

Airway Pressures

Airway pressures are routinely measured during mechanical ventilation and provide a plethora of useful information. The electromechanical transducers that convert pressure to electrical current are often located either in the ventilator circuit or, sometimes, the esophagus. The term *airway pressure* (P_{AW}) refers to pressure measured within the ventilator circuit, while pressure measured within the esophagus is referral to as *esophageal pressure* (P_{ES}). P_{ES} is thought of as a surrogate for pleural pressure, which is difficult to directly measure in routine practice.[110]

A number of pressure measurements are commonly made during the respiratory cycle, including peak airway pressure (Ppeak), plateau pressure (Pplat), mean airway pressure (Pmean), driving pressure (ΔP), positive end-expiratory pressure (PEEP), and autoPEEP or intrinsic PEEP.[111]

Ppeak (Fig. 146-3) represents the total pressure the ventilator must generate to overcome the impedance of the respiratory system, including airflow resistance, load imposed by distention of the lung and chest wall, and any load imposed by other factors, such as dynamic hyperinflation or increased intra-abdominal pressure. Ppeak is governed by several factors, including inspiratory flow rate, the inspiratory waveform (ramp versus square), and the tidal volume.

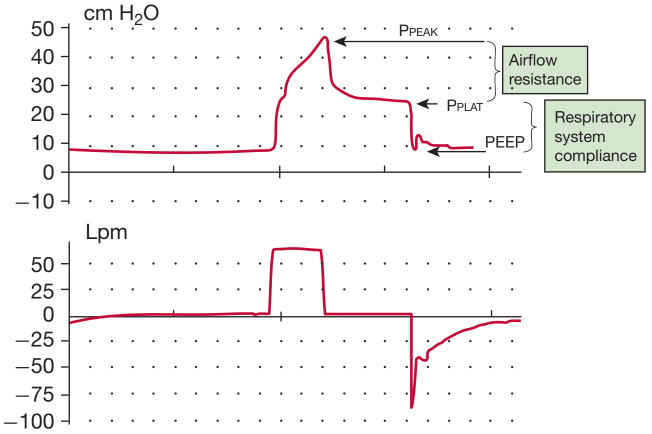

Figure 146-3 Inspiratory hold maneuver during constant flow in a volume-controlled breath. Note the significant difference between the patient's peak airway pressure (48 cm H_2O) and plateau pressure (26 cm H_2O), indicative of increased airway resistance.

Pplat (Fig. 146-3) is a measure of end-inspiratory alveolar pressure and is measured by applying an end-inspiratory breath hold that allows pressure to equilibrate throughout the respiratory system once flow has ceased. Pplat should always be lower than Ppeak, and the pressure difference between the two reflects the pressure needed to drive airflow through the respiratory tree into the alveoli. Relatedly, the driving pressure (ΔP) is calculated as Pplat − PEEP and is reflective of the respiratory system compliance.[112]

In patients with high airway pressures, the problem could be either resistive (due to high airway resistance) or elastic (lung and chest wall apparatus) issues. This can be quickly characterized by determining the difference between Ppeak and Pplat, as well as the driving pressure (Fig. 146-3). If Ppeak − Pplat increases while the driving pressure remains unchanged, it strongly suggests an issue with airflow resistance, such as mucus plugging, bronchospasm, or otherwise obstructed ETT. In contrast, an increase in driving pressure suggests decreased lung or chest wall compliance, which can stem from a variety of issues including pleural effusion, pneumothorax, alveolar filling processes, single mainstem bronchus intubation, or increases in intra-abdominal pressure.[111] Attempts to correct a high Ppeak in a patient with obstructive lung disease by reducing the inspiratory flow may paradoxically result in increased auto PEEP and Ppeak due to insufficient expiratory time.[111] The resulting increase in Pplat may heighten the risk of barotrauma.

AutoPEEP, also known as intrinsic PEEP, refers to the pressure exerted by gas that is left over in the alveoli at the end of expiration. There are three common situations in which autoPEEP develops, including high minute ventilation, expiratory flow limitation, and expiratory resistance. High minute ventilation can be caused by either large tidal volumes, high respiratory rates, or both; both situations can make it more difficult for the patient to fully exhale the entirety of the tidal volume.[113] Expiratory flow limitation is usually the result of airway narrowing due to bronchospasm, inflammation, or scarring, and is a common cause of autoPEEP in patients with chronic obstructive pulmonary disease. Expiratory resistance is a similar concept, except that it is unrelated to the airways and generally refers to the rest of the respiratory apparatus, such as a narrow or kinked ETT, the presence of a PEEP valve, or tenacious ETT secretions.[114]

In mechanically ventilated patients, autoPEEP is generally identified by examining the flow–time waveform to verify that the expiratory flow curve returns to baseline before the next breath is delivered (Fig. 146-4). The magnitude of autoPEEP can be quantified

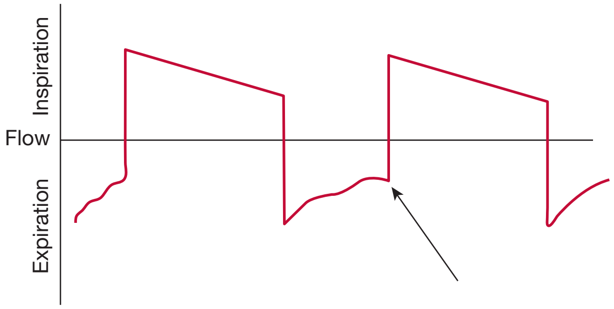

Figure 146-4 The presence of auto-PEEP is identified from the flow waveform. The next breath commences before expiratory flow returns to zero.

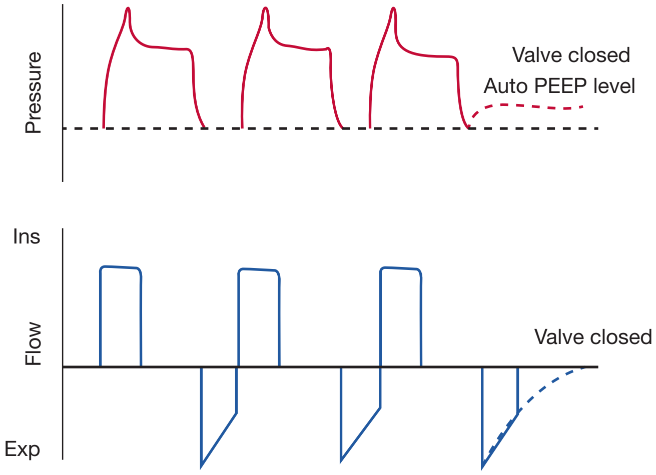

Figure 146-5 Expiratory hold technique to quantify auto-PEEP. The expiratory valve is closed during an expiratory "hold" at the end of a set expiratory time. When flow equals zero, airway pressure rises to the auto-PEEP level.

by doing an expiratory hold maneuver, which allows pressures to equilibrate throughout the respiratory system (Fig. 146-5). The total PEEP "experienced" by the alveoli is then calculated as the sum of the measured autoPEEP and the PEEP applied by the ventilator.[115] While measurement of autoPEEP is generally easily accomplished, active respiratory efforts by the patient may preclude accurate measurement of autoPEEP, which may necessitate heavy sedation or paralysis if measurements are needed.[114]

Calculation of the aforementioned pressures facilitates an understanding of other important measures of respiratory mechanics, particularly respiratory system compliance (Crs), elastance, and airway resistance (Raw). Compliance is defined as the change in lung volume (tidal volume) divided by the driving pressure (the difference between Pplat and total PEEP). Normal Crs is generally >60 mL/cm H_2O. Elastance is defined as the inverse of compliance (1/compliance).[111]

Lung-protective ventilation aims to reduce ventilator-induced lung injury (VILI) by setting low tidal volumes and targeting a Pplat less than 30 cm H_2O.[116–119] This is predicated on the idea that such practices reduce mechanical end-expiratory lung stress, strain, and atelectrauma in patients with ARDS.[120] However, even reduced tidal volumes based on ideal body weight may generate lung injury due to the reduced volume of lung available for ventilation (i.e., the "baby lung" concept).[121] Recent studies have suggested that among ventilation variables, including tidal volume and plateau pressure, driving pressure is the variable that best stratifies risk of mortality.[122] Although it has been suggested that titrating PEEP to target a driving pressure of 15 cm H_2O or less could lead to improved patient outcomes, only observational studies exist supporting the effects of driving pressure optimization on outcomes; prospective randomized controlled trials may be needed.[121–124]

Esophageal Pressure

Quantification of the pleural pressure can be useful, as it permits calculation of the transmural distending pressure of the lung and allows characterization of the compliance of the entire lung and chest wall apparatus. Pleural pressure is difficult to routinely measure but may be useful in certain patients where the underlying etiology of respiratory failure is difficult to determine. Esophageal pressure (P_{ES}) is considered a surrogate for pleural pressure and can be estimated using a balloon-tipped esophageal catheter, typically inserted to a depth of approximately 40 cm in order to minimize artifact from cardiac oscillations.[110] While a small study suggested improved outcomes with the use of esophageal catheters to titrate PEEP in patients with ARDS, a larger, randomized, controlled trial (EPVENT2) suggested that a P_{ES}-guided PEEP strategy (compared with empiric PEEP titration) did not improve outcomes in patients with moderate to severe ARDS.[120] Therefore, given the complexities involved in its use, esophageal pressure remains predominantly a research tool.

■ Ventilator Waveforms

All mechanical ventilators are equipped with a spirometer that enables monitoring of flow and volume of gas being exchanged during the respiratory cycle. These data are graphically represented on the ventilator screen as waveforms, most commonly flow, pressure, and volume plotted over time. A keen understanding of these waveforms is crucial to detecting development of autoPEEP, patient-ventilator dyssynchrony, airway obstruction, worsening compliance, and a variety of other issues.

Pressure–Time Waveform

The pressure waveform graphed over time is particularly useful in volume-cycled modes of ventilation, as pressure is the dependent variable. Examination of the waveform can yield important information, such as whether the patient is initiating breaths (negative deflection before delivery of tidal volume), the amount of work needed to trigger inspiration (the amplitude of the negative deflection), whether inspiratory flow is sufficient to meet the patient's needs (Fig. 146-6, demonstrating downward deflection during inspiration), and whether the set inspiratory time is too long or too short compared with the patient's "neural" inspiratory time. An inspiratory and expiratory hold can also be performed at the bedside and help determine compliance, resistance, and autoPEEP.

Flow–Time Waveform

In volume-cycled modes of ventilation the flow rate and pattern are set by the clinician, so examination of the flow waveform is most useful in pressure-cycled modes. In pressure-control ventilation, inspiratory time is set and thus governs inspiratory flow, which should cease prior to onset of exhalation. If this does not happen, inspiratory time should be adjusted. In pressure support ventilation, where inspiratory time may vary, flow is important in determining when exhalation is triggered; typically, exhalation begins when inspiratory flow reaches 25% of the peak flow. This threshold may need to be altered in patients with obstructive lung disease due to high lung compliance in that population. The expiratory limb of the flow waveform can also be scrutinized to help detect autoPEEP. Expiratory flow that fails to cease before the next breath is delivered suggests the presence of autoPEEP (assuming no active respiratory effort), which can be quantified with an expiratory hold.

■ Respiratory Muscle Strength

Measurements of respiratory muscle strength can be important to identify neuromuscular weakness as a cause of respiratory failure; recent technology may be helpful to monitor for development of diaphragmatic weakness as occurs with critical illness myopathy.

Inspiratory and Expiratory Pressure

Assessment of respiratory muscle strength generally involves measuring maximal inspiratory pressure (MIP), also known as negative inspiratory force (NIF) and, less commonly, maximal expiratory pressure (MEP). Each measurement is compared with reference ranges according to a patient's age and sex. MIP is measured at functional residual capacity and is generally performed while the patient is connected to the ventilator by performing an expiratory hold and measuring the magnitude of the negative pressure deflections over

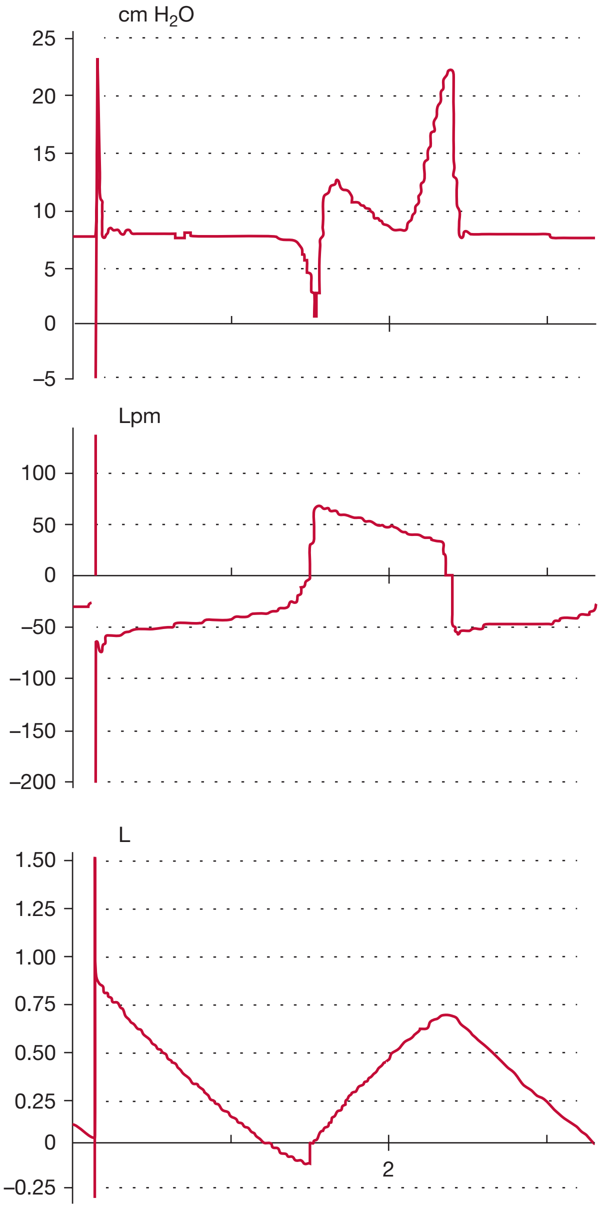

Figure 146-6 Patient-ventilator dyssynchrony during volume-controlled ventilation, secondary to inadequate flow.

10 consecutive inspirations or 30 s. MEP is measured at total lung capacity, but it is not routinely used in clinical practice except in certain patient populations.[125]

Diaphragm Ultrasound

In recent years, there has been growing interest in using ultrasound to evaluate diaphragm function. In general, diaphragm ultrasound (DUS) can be used in two ways: to measure changes in diaphragm thickness or to quantify diaphragm excursion. Diaphragm thickness can be measured by placing a high-frequency linear probe at the *zone of apposition*—the vertical regions of the hemidiaphragms that are directly apposed to the ribs of the lower chest wall. Thickness at end-inspiration and end-expiration are used to calculate a "thickening fraction." Although several studies have shown that the diaphragm undergoes changes in thickness during mechanical ventilation detectable by ultrasound, it is not clear that this correlates to diaphragmatic weakness or differences in outcome. Measurement of diaphragm excursion can be performed by placing a phased-array or curvilinear probe in an anterior subcostal position and identifying the diaphragm. Movement of the diaphragm toward and away from the probe is then quantified, with less than a normal amplitude of diaphragm excursion suggesting weakness, and absent or paradoxical motion suggesting diaphragm paralysis.[126] Diaphragm ultrasound may have a role in patients with ARF, including estimating work of breathing in patients undergoing noninvasive ventilation,[127] detecting diaphragm weakness or paralysis,[128] and assessing probability of success weaning from mechanical ventilation.[129]

Diaphragm Electromyography

Electromyography (EMG) is a spatiotemporal summation of neural impulses that are transformed into muscle action potentials. Diaphragm EMG has garnered increasing interest over recent years due to growing recognition of the diaphragm's role in respiratory failure, particularly in patients with prolonged mechanical ventilation and difficulty weaning from the ventilator. Diaphragm EMG is best recorded using an esophageal catheter with multiple electrodes; the processed signal is referred to as the *amplitude of the electrical activity of the diaphragm* (EADi). There is great interest in using EADi to detect patient–ventilator asynchrony, to monitor respiratory muscle unloading during mechanical ventilation, and to assess efficacy of breathing in critically ill patients, including those on ECMO.[130] However, this technology is still making the transition to the bedside and requires further study before it is ready for widespread use in clinical practice.

CHAPTER 147

Principles of Mechanical Ventilation

Martin J. Tobin

INTRODUCTION

The pivotal importance of mechanical ventilation was highlighted in the early days of the COVID-19 pandemic when scientific societies issued guidelines on how to connect four patients to a single machine, and politicians pleaded with automakers to branch into the manufacture of ventilators.[1]

Given the panic and pandemonium, the prediction that patients were being inappropriately intubated and ventilated was quickly borne out, as 90% or more of patients were intubated in some intensive care units.[2,3] The number of deaths that resulted from unnecessary use of invasive mechanical ventilation will never be known, but it is likely to have been very high.[4] A sound understanding of the principles of mechanical ventilation is vitally important for every pulmonary and critical care physician.

OBJECTIVES AND INDICATIONS FOR MECHANICAL VENTILATION

The objectives of mechanical ventilation are listed in Table 147-1.[5] Authors have listed criteria to guide intubation, but none has stood the test of rigorous investigation.[1,6] Measurements such as oxygen saturation help, but it is not possible to pick a saturation breakpoint at which the benefits of mechanical ventilation will decidedly outweigh its hazards across all patients.[2] The decision to insert an endotracheal tube is, instead, based on clinical judgment, gestalt, and tacit knowledge individualized to each particular patient.[1,6]

Increased work of breathing is the most common reason for intubation.[6] Accurate measurement of work of breathing involves inserting an esophageal balloon to measure inspiratory effort, which requires a certain technical skill.[7] More practical is estimation of work of breathing based on meticulous physical examination. The key step is gently touching the sternomastoid muscle with the index finger, checking for phasic—not tonic—contraction, and then judging its magnitude qualitatively (Fig. 147-1).[8] Next is placing the index finger on the cricoid cartilage and judging the presence and degree of tracheal tug (Fig. 147-2). Then, inspecting the suprasternal fossa and the intercostal spaces for recession is performed (Figs. 147-3 and 147-4). The physician integrates these physical signs into the clinical context and judges if respiratory work is sustainable, or if assisted ventilation (invasive or noninvasive) is more prudent.[1,6,8]

Increased respiratory work increases the oxygen cost of breathing to as much as 50% of total oxygen consumption.[9] By decreasing respiratory work, mechanical ventilation allows precious oxygen stores to be rerouted to other vulnerable tissue beds. To substantially reduce patient effort, the ventilator must cycle in unison with

TABLE 147-1 Objectives of Mechanical Ventilation

Improve pulmonary gas exchange
Reverse hypoxemia
Relieve acute respiratory acidosis
Relieve respiratory distress
Decrease oxygen cost of breathing
Reverse respiratory muscle fatigue
Alter pressure–volume relationships
Prevent or reverse atelectasis
Improve lung compliance
Prevent further lung injury
Permit lung and airway healing
Avoid complications

the patient's central respiratory rhythm (Fig. 147-5).[10] For perfect synchronization, the period of mechanical inflation must match the period of neural inspiratory time (the duration of inspiratory effort), and the period of mechanical inactivity must match the neural expiratory time.[11] Work of breathing is increased in patients with atelectasis or acute lung injury because breathing occurs on the low, flat portion of the pressure–volume curve. By shifting tidal ventilation to the steep, compliant portion of the curve, mechanical ventilation can decrease respiratory work.

Acute progressive respiratory acidosis is a classic indication for mechanical ventilation, although simpler measures can sometimes reverse the process.[7] For example, among patients with acute severe asthma and hypercapnia, hypercapnia resolves with standard bronchodilator therapy, without the need for mechanical ventilation, in more than 90% of patients.[12] If a patient has severe respiratory depression that is expected to be slow in resolving (e.g., in certain drug overdoses), intubation and mechanical ventilation should be instituted without delay.

Hypoxemia is not a common reason for intubation and mechanical ventilation. In critically ill patients, hypoxemia is usually caused by an amalgam of ventilation–perfusion mismatch and shunt physiology. When ventilation–perfusion mismatch prevails, arterial oxygen tension ($\mathrm{Pa}_{\mathrm{O}_2}$) increases substantially in response to supplemental oxygen; a satisfactory level of arterial oxygenation is usually sustained in these patients without recourse to intubation (and mechanical ventilation).[1] When intrapulmonary shunt is dominant, the increase in $\mathrm{Pa}_{\mathrm{O}_2}$ with supplemental oxygen is modest or absent. Intubation helps by ensuring delivery of a high fractional inspired oxygen concentration ($\mathrm{FI}_{\mathrm{O}_2}$), and positive-pressure ventilation helps by recruiting collapsed lung units, leading to improved matching of ventilation and perfusion.[6]

Patient self-inflicted lung injury (P-SILI) is a new condition postulated to justify pre-emptive endotracheal intubation in patients breathing vigorously; P-SILI attracted considerable coverage in the context of COVID-19.[2] Studies put forward to support the existence of P-SILI are circumstantial and weak, and there is no robust experimental evidence to prove that P-SILI actually occurs in patients.[3] Several studies have now revealed that alacrity in intubation of COVID-19 patients is associated with higher mortality. In one series, mortality decreased from 44% in February and March to 34% in April and May of 2020 in conjunction with a decrease in the rate of intubation from 76% in the first time frame to 44% in the second.[13]

Commonly listed indications for mechanical ventilation include acute respiratory failure, exacerbation of chronic respiratory failure (secondary to infection, bronchoconstriction, or heart failure), coma, and neuromuscular disease. Many patients with these same conditions, however, are managed without ventilator assistance. Indeed, the most common, and honest, reason that mechanical ventilation is instituted is a tautology: A physician thinks that "the patient looks like he (or she) needs to be placed on the ventilator."[6] Mechanical ventilation is most commonly instituted based on a physician's clinical gestalt, formed through assessing a patient's signs and symptoms, rather than because a patient satisfies a certain set of criteria on a checklist. It is important to ground this decision on solid knowledge of pulmonary pathophysiology.

MODES OF MECHANICAL VENTILATION

The term *mode* refers to the relationship among various breath types (mandatory, assisted, supported, and spontaneous), as well as inspiratory phase variables.

■ Controlled Mechanical Ventilation

In controlled mechanical ventilation, the ventilator delivers all breaths at a preset rate, and the patient cannot trigger the machine.

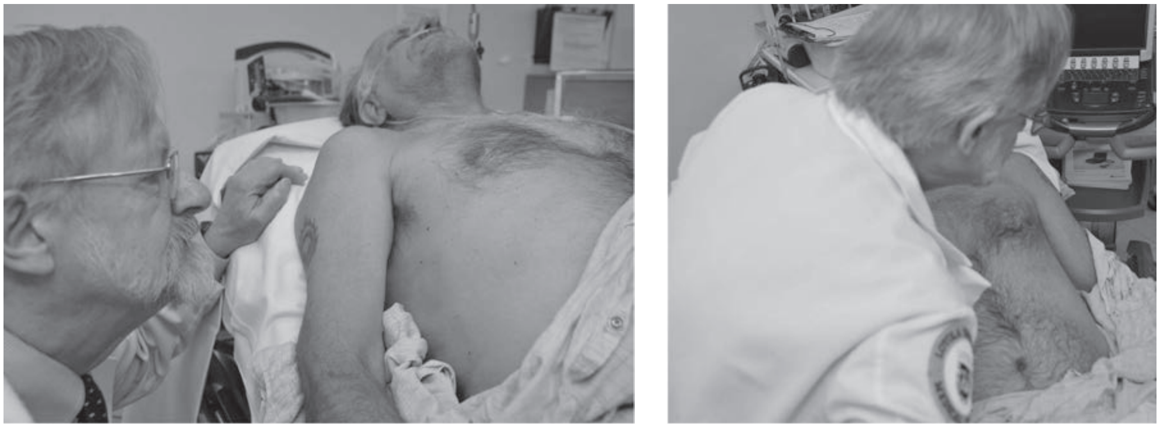

Figure 147-4 Inspecting the ipsilateral intercostal spaces to judge for the presence of inspiratory recession *(left)*. Sometimes recession is easier to detect upon inspecting the profile of the contralateral hemithorax *(right)*. When inspecting each hemithorax, the clinician should also check for Hoover sign, a paradoxical inward motion of the lower rib cage during inspiration, signifying a flattened and disadvantaged diaphragm. *(Reproduced with permission from Tobin MJ. Why Physiology Is Critical to the Practice of Medicine: A 40-year Personal Perspective. Clin Chest Med. 2019;40(2):243–257.)*

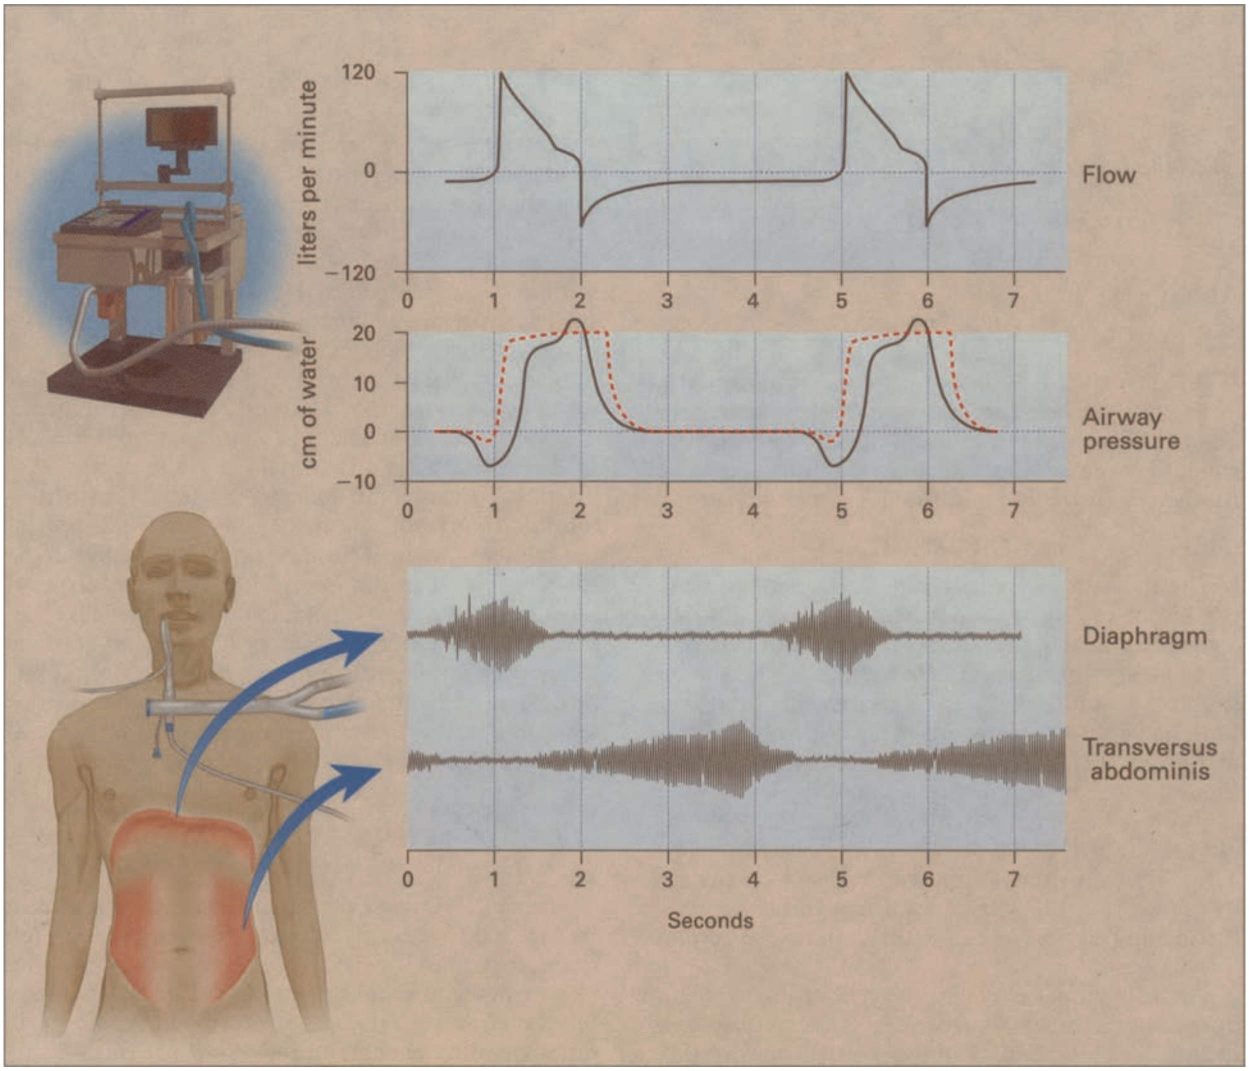

Figure 147-5 Flow, airway pressure, and inspiratory and expiratory muscle activity in a patient with chronic obstructive pulmonary disease who received pressure-support ventilation at an airway pressure of 20 cm H_2O. The electromyograms in the *lower portion* of the figure show inspiratory muscle activity in the patient's diaphragm and expiratory muscle activity in the transversus abdominis. The patient's increased inspiratory effort caused the airway pressure to fall below the set sensitivity (−2 cm H_2O), and inadequate delivery of flow by the ventilator resulted in a scooped contour on the airway–pressure curve during inspiration. While the ventilator was still pumping gas into the patient, his expiratory muscles were recruited, causing a bump in the airway–pressure curve. That the flow never returned to zero throughout expiration reflected the presence of PEEPi. The *broken red line* shows airway pressure in another patient, who generated just enough effort to trigger the ventilator and in whom there was adequate delivery of gas by the ventilator. *(Reproduced with permission from Tobin MJ. Advances in mechanical ventilation. N Engl J Med. 2001;344(26):1986–1996. Data from Jubran A, Van de Graaff WB, Tobin MJ. Variability of patient-ventilator interaction with pressure support ventilation in patients with chronic obstructive pulmonary disease. Am J Respir Crit Care Med. 1995;152: 129–136; Parthasarathy S, Jubran A, Tobin MJ. Cycling of inspiratory and expiratory muscle groups with the ventilator in airflow limitation. Am J Respir Crit Care Med. 1998;158:1471–1478.)*

In the volume-targeted mode, the breaths have a preset volume—so-called volume-controlled ventilation. When the breaths are pressure limited and time cycled, the mode is termed *pressure-controlled* ventilation. Use of volume-controlled ventilation is largely restricted to patients who are apneic as a result of brain damage, sedation, or paralysis.

■ Assist-control Ventilation

In the assist-control mode, the ventilator delivers a breath either when triggered by the patient's inspiratory effort (pressure or flow triggered) or, independently, if such an effort does not occur within a preselected time period.[14] All breaths are delivered under positive pressure by the machine, but unlike controlled mechanical ventilation, the patient's triggering effort can exceed the preset rate. If the patient's spontaneous rate drops below the preset back-up rate, controlled ventilation is provided. The breath delivered by the ventilator may have a predetermined volume (volume-cycled form of assist-control ventilation) or a predetermined inflation pressure that is applied for a predetermined inflation time (pressure control form of assist-control ventilation). By design, delivered tidal volume (V_T) is not influenced by patient effort. The greater the inspiratory effort made by the patient, the lower will be the airway pressure during the volume-cycled form of assist-control ventilation, such that the overall airway pressure on the ventilator monitor bears an inverse relationship to patient-generated pressure.

The ventilator cycles off when the preset V_T is reached, and machine inspiratory time may be shorter or longer than the patient's intrinsic (neural) inspiratory time.[11] If the set V_T is reached before the end of neural inspiratory time, the machine cycles off while the patient's inspiratory effort continues. If the patient's inspiratory effort ceases before the set V_T is reached, the machine increases pressure to provide continued inspiratory flow. The amount of active work performed by a patient ventilated in the assist-control mode is critically dependent on the trigger sensitivity and inspiratory flow settings. Even when these settings are selected appropriately, patients actively perform about one-third of the work performed by the ventilator during passive conditions.[15]

Intermittent Mandatory Ventilation

With intermittent mandatory ventilation (IMV), the patient receives periodic positive-pressure breaths from the ventilator at a preset volume and rate, but the patient can also breathe spontaneously between these mandatory breaths.[16] A problem unforeseen at the time IMV was introduced is the difficulty that patients encounter in trying to adapt to the intermittent nature of ventilator assistance. It had been assumed that the degree of respiratory muscle rest achieved by IMV would be proportional to the number of mandatory breaths delivered. Studies, however, have demonstrated that inspiratory effort is equivalent for spontaneous and assisted breaths during IMV (Fig. 147-6).[17,18] Indeed, the tension–time index for both spontaneous and assisted breaths is above the threshold associated with respiratory muscle fatigue at IMV rates of 14 breaths/min or less.[17] At a moderate level of machine assistance (at which the ventilator accounts for 20% to 50% of total ventilation), electromyographic activity of the diaphragm and sternocleidomastoid muscles is equivalent for assisted and spontaneous breaths.[18] These findings suggest that respiratory center output is preprogrammed and does not adjust to breath-to-breath changes in load, as occurs during IMV. As a result, IMV may contribute to development of respiratory muscle fatigue or prevent its recovery.

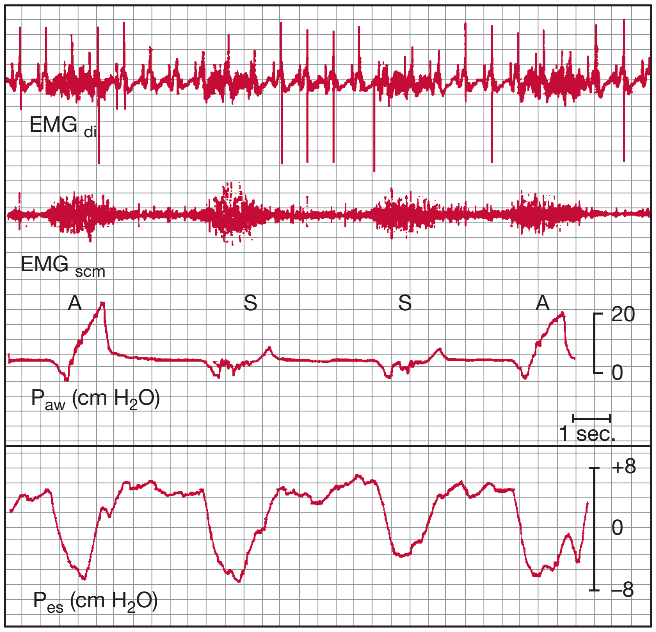

Figure 147-6 Electromyograms of the diaphragm (EMGdi) and sternocleidomastoid muscles (EMGscm) in a patient receiving synchronized intermittent mandatory ventilation. Similar intensity and duration of electrical activity during assisted (**A**) and spontaneous (**S**) cycles are demonstrated. P_{aw}, airway pressure; P_{es}, esophageal pressure. *(Reproduced with permission from Imsand C, Feihl F, Perret C, et al. Regulation of inspiratory neuromuscular output during synchronized intermittent mechanical ventilation. Anesthesiology. 1994;80(1):13–22.)*

Pressure-support Ventilation

Pressure-support ventilation is patient triggered, like assist-control ventilation and IMV, but it differs in that it is pressure targeted and flow cycled.[19] The physician sets a level of pressure that augments every spontaneous effort, and the patient may alter respiratory frequency, inspiratory time, and V_T. V_T is determined by the pressure setting, the patient's effort, and pulmonary mechanics, in contrast to assist-control ventilation and IMV, in which a guaranteed volume is delivered. With volume-targeted ventilation, the inspiratory flow setting is a crucial determinant of patient work. There is no flow setting with pressure-support ventilation, although the initial peak flow determines the speed of pressurization and the initial pressure ramp profile.

Pressure support can be very effective in decreasing the work of inspiration. The degree of inspiratory muscle unloading, however, is variable, with a coefficient of variation of up to 96% among patients.[20] The level of pressure delivered by the ventilator is usually adjusted in accordance with changes in the patient's respiratory frequency. The respiratory frequency, however, that signals a satisfactory level of respiratory muscle rest has never been well defined, and recommendations range from 16 to 30 breaths/min.[20]

Cycling to exhalation is triggered by a decrease in inspiratory flow to a preset level, such as 5 L/min or 25% of peak inspiratory flow, depending on the manufacturer's algorithm (Fig. 147-7). The algorithm for "cycling off" of mechanical inflation causes problems in patients with COPD because increases in resistance and compliance produce a slow time constant (of the respiratory system). The longer time needed for flow to fall to the threshold value may cause mechanical inflation to persist into neural expiration.

In 12 patients with COPD receiving pressure support of 20 cm H_2O, Jubran et al.[20] found that 5 recruited their expiratory muscles while the machine was still inflating the thorax. The patients who recruited their expiratory muscles during mechanical inflation had an average time constant of 0.54 s, compared with an average of 0.38 s in patients who did not exhibit expiratory muscle activity. The persistence of mechanical inflation into neural expiration is very

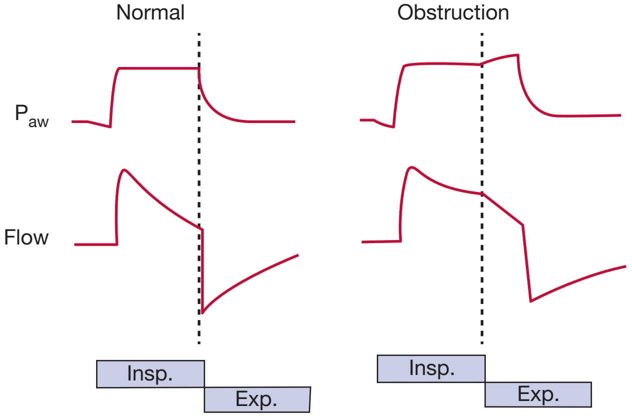

Figure 147-7 Airway pressure (P_{aw}) and inspiratory (Insp) and expiratory (Exp) flow during pressure-support ventilation in patients with normal and obstructed airways. Patient effort triggers the ventilator to deliver a preset pressure, and inspiratory assistance continues until the flow rate falls to 25% of the peak inspiratory flow. In patients with airway obstruction, who have a prolonged time constant, more time is required for flow to decrease to this threshold value, so that neural expiration commences before the termination of mechanical inflation. The resulting activation of the expiratory muscles hastens the fall in flow, but it also results in dyssynchrony between the patient's neuromuscular activity and the mechanical phase of the ventilator—so-called "fighting the ventilator."

uncomfortable, as well recognized with use of inverse-ratio ventilation (where, contrary to the normal pattern, inflation lasts longer than exhalation).

New Modes

New modes of mechanical ventilation are frequently introduced. Each has an acronym, and the jargon is inhibiting to those unfamiliar with it. Yet each new mode involves nothing more than a modification of the manner in which positive pressure is delivered to the airway and of the interplay between mechanical assistance and the patient's respiratory effort.[10] The purpose of a new mode may be to enhance respiratory muscle rest, prevent deconditioning, improve gas exchange, prevent lung damage, enhance coordination between ventilator assistance and patient respiratory effort, and foster lung healing. The priority given to each goal varies.

VENTILATOR SETTINGS

Ventilator settings are based on the patient's size and clinical condition. Determination of the settings is a dynamic process, based on a patient's physiologic response, rather than on a fixed set of numbers.[21] The settings require repeated readjustment over the period of ventilator dependency. Such an iterative process requires careful respiratory monitoring.

Triggering

Many ventilators employ pressure triggering, whereby a decrease in circuit pressure is required to initiate ventilator assistance. Patients reach the set sensitivity by activating their inspiratory muscles. When the threshold is reached, however, inspiratory neurons do not simply switch off.[7] Consequently, the patient may expend considerable inspiratory effort throughout a machine-cycled inflation. The level of patient effort during this post-trigger phase is closely related to a patient's respiratory motor output at the point of triggering.[22] As such, measures that decrease respiratory drive may enhance respiratory muscle rest during mechanical ventilation.

If respiratory motor output at the point of triggering is important, one might expect that effort during the time of triggering would determine patient effort during the remainder of inspiration. To elucidate this issue, Leung et al.[22] applied graded levels of pressure support in 11 critically ill patients. They achieved a fourfold reduction in overall patient effort. Yet patient effort during the time of triggering did not change. The constancy of effort during the trigger phase was probably secondary to different factors becoming operational as the level of ventilator assistance was varied (Fig. 147-8). Thus, increases in the level of ventilator assistance do not substantially decrease patient effort during the time of triggering.

The display of airway pressure and flow tracings on ventilator screens has increased awareness that inspiratory effort is frequently insufficient to trigger the ventilator.[10,11] At high levels of mechanical assistance, up to one-third of a patient's inspiratory efforts may fail to trigger the machine (Fig. 147-9). The number of ineffective triggering attempts increases in direct proportion to the level of ventilator assistance. Surprisingly, unsuccessful triggering is not the result of poor inspiratory effort.

In a study of factors contributing to ineffective triggering, effort was noted to be more than one-third greater when the threshold for triggering the ventilator was not reached than when it was.[22] Breaths that do not reach the threshold for triggering the ventilator have higher V_T and shorter expiratory time than do breaths that do trigger the ventilator. Consequently, elastic recoil pressure builds up within the thorax in the form of PEEPi. To trigger the ventilator, the patient's inspiratory effort has to first generate a negative intrathoracic pressure in order to counterbalance the elastic recoil; it then must reach the set sensitivity.

The time at which a patient initiates an expiratory effort (in relation to the cycling of the ventilator) partly determines the success of the ensuing inspiratory effort in triggering the machine. The relationship between the onset of expiratory muscle activity and termination of mechanical inflation by the ventilator has been quantified.[23] At a pressure support of 20 cm H_2O, mechanical

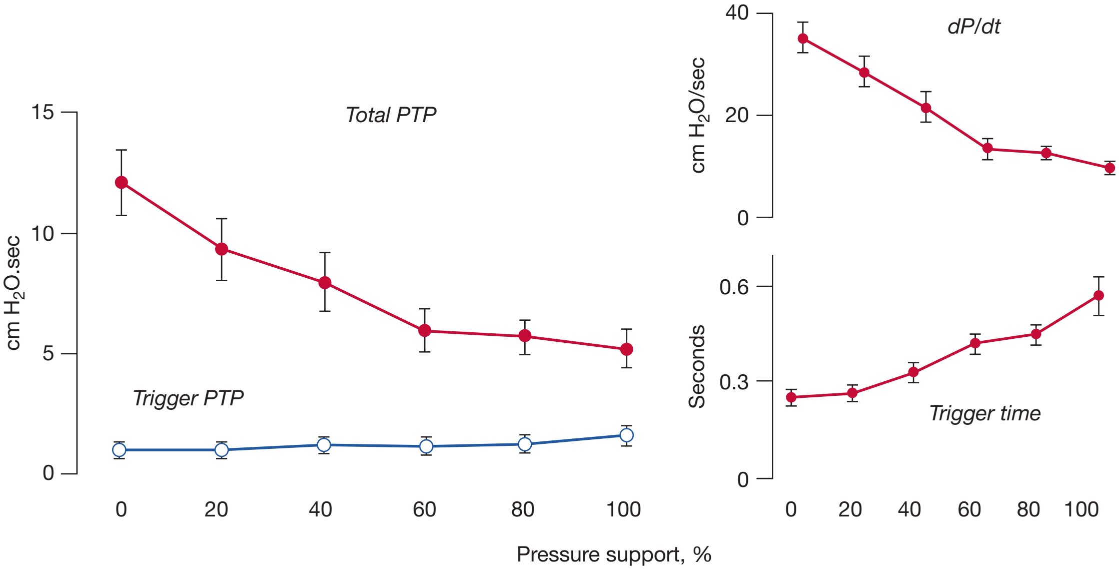

Figure 147-8 Graded increases in pressure support produced a decrease in total pressure–time product (PTP) per breath *(closed symbols)*, although PTP during the trigger phase *(open symbols)* did not change *(left panel)*. The constancy of PTP during triggering probably resulted from different factors becoming operational at different levels of assistance *(right panel)*. At low levels of pressure support, respiratory drive (dP/dt) and PEEPi were high, but triggering time was short, resulting in a large change in pleural pressure over a brief interval. At high levels of pressure support, dP/dt and PEEPi were low, but triggering time was long, resulting in a smaller change in pleural pressure over a longer time. *(Data from Leung P, Jubran A, Tobin MJ. Comparison of assisted ventilator modes on triggering, patient effort, and dyspnea. Am J Respir Crit Care Med. 1997;155:1940–1948; Tobin MJ, Jubran A, Laghi F. Patient ventilator interaction. Am J Respir Crit Care Med. 2001;163:1059–1063.)*

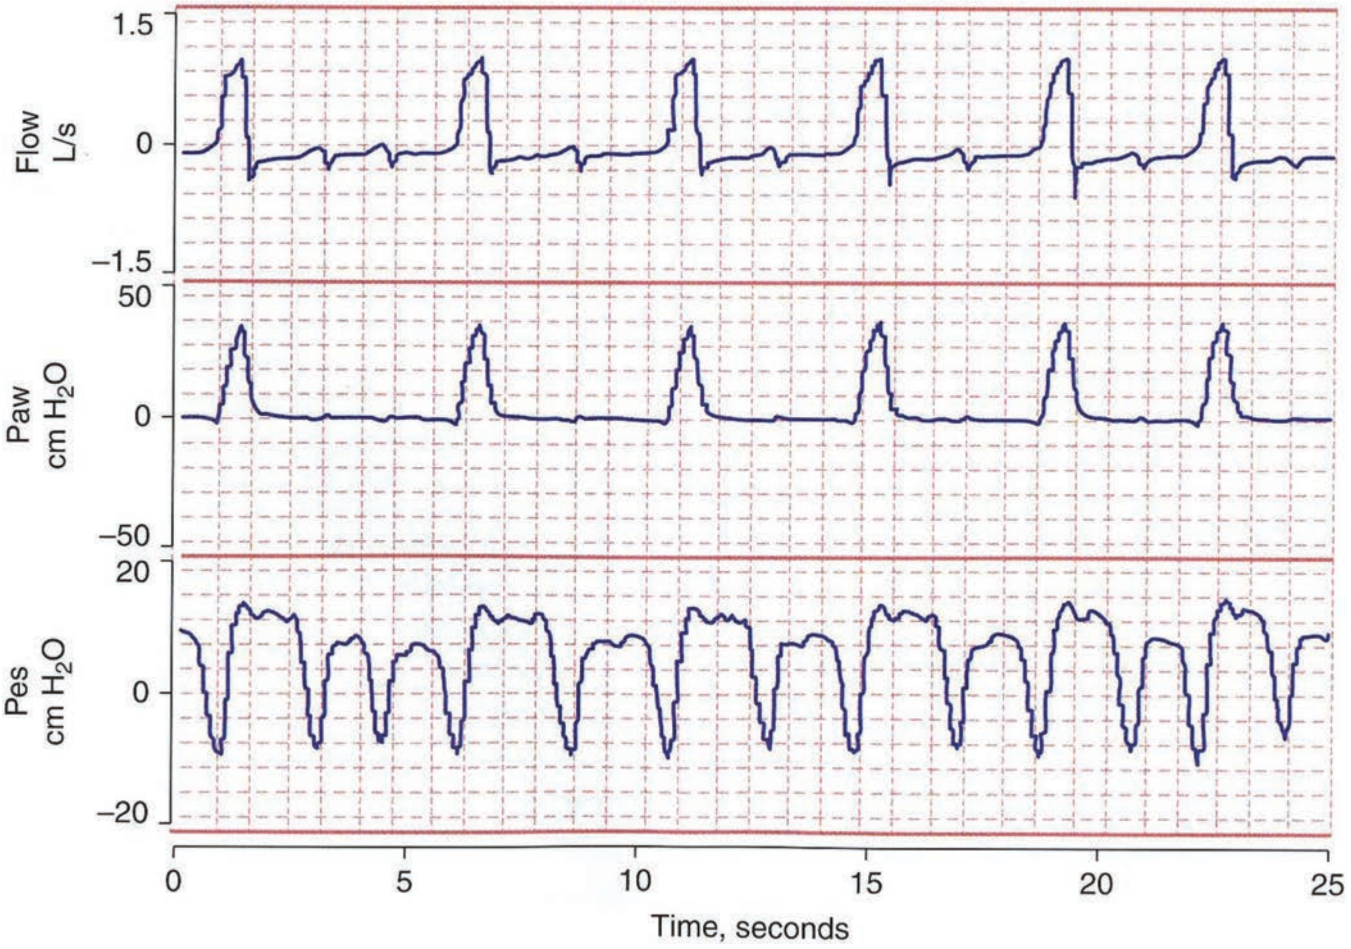

Figure 147-9 Failure to trigger the ventilator. Flow, airway pressure (Paw), and esophageal pressure (Pes) in a patient with COPD who is receiving assist-control ventilation at the following settings: tidal volume 600 mL, inspiratory flow 60 L/min, trigger sensitivity −2 cm H_2O, and positive end-expiratory pressure 0 cm H_2O. The patient's intrinsic respiratory rate is 28 breaths/min, whereas the number of breaths delivered by the ventilator is 16 breaths/min. That is, 43% of the patient's inspiratory efforts fail to trigger ventilator assistance. Contractions of the inspiratory muscles during the failed triggering attempts cause a temporary deceleration of expiratory flow and much less obvious decreases in airway pressure. The temporary decelerations in expiratory flow are followed by temporary accelerations of expiratory flow that coincide with the termination of the unsuccessful inspiratory effort. *(Reproduced with permission from Tobin MJ, Laghi F, Jubran A. Ventilatory failure, ventilator support, and ventilator weaning. Compr Physiol. 2012;2(4):2871–2921.)*

inflation continues for a longer time into neural expiration in the breaths preceding nontriggering attempts. Continuation of mechanical inflation into neural expiration counters expiratory flow, and it also decreases the time available for unopposed exhalation. Consequently, elastic recoil increases. In turn, a greater inspiratory effort will be needed to achieve effective triggering. In this way, the time at which a patient commences an expiratory effort (in relation to cycling off of mechanical inflation) partly determines the success of the ensuing inspiratory effort in triggering the ventilator.

■ Tidal Volume

Tidal volume (V_T) has become the most misunderstood ventilator setting and a source of considerable torment to patients. V_T of 12 mL/kg is the only ventilator setting proven to influence patient mortality in randomized clinical trials (RCTs).[24–26] Because the RCTs involved a comparison of V_T of 12 mL/kg versus 6 mL/kg, guidelines promoted 6 mL/kg as the ideal V_T—not only in patients with acute respiratory distress syndrome (ARDS) but extrapolated (irrationally) to all ventilated patients. In reality, V_T of 6 mL/kg has not been proven superior to 11 mL/kg (or anything in between).[26]

In five RCTs of V_T in patients with ARDS, the sole physiologic variable that discriminated between the two positive RCTs[24,25] and the three negative RCTs[27–29] was the average airway plateau pressure. Patients with significantly increased mortality had plateau pressures greater than 32 cm H_2O.[30] It never made sense physiologically to advocate setting V_T in terms of mL per kg because it ignores the physiologic variable (plateau pressure) that signals alveolar injury.[7,10] This is analogous to basing pharmacotherapy in a patient with a hypertensive emergency on milligram dosage and ignoring changes in arterial blood pressure.[30] The most recent reanalyses of data from the five RCTs of high versus low V_T have finally come around to stating that V_T should not be based on mL per kg.[31,32]

Critically ill patients have inflamed lungs, and stimulation of sensory receptors produces heightened respiratory drive and dyspnea.[1,33] Dyspneic patients react by attempting deeper inspirations. When a low V_T setting impedes this response, intense dyspnea is guaranteed through corollary discharge from the medulla oblongata to the cerebral cortex.[34] Dyspnea is amplified by hypercapnia that is axiomatic with hypoventilation; an increase in Pa_{CO_2} from 45 to 50 mm Hg induces an increase in minute ventilation of 25 L/min and tremendous air hunger.[33] Patients rebel against the racking constraint—air hunger—and buck the ventilator.[35] Caregivers use sedative and paralyzing agents to combat recalcitrant patients and restrain them on the Procrustean bed of 6 mL/kg.[32] Sedative agents

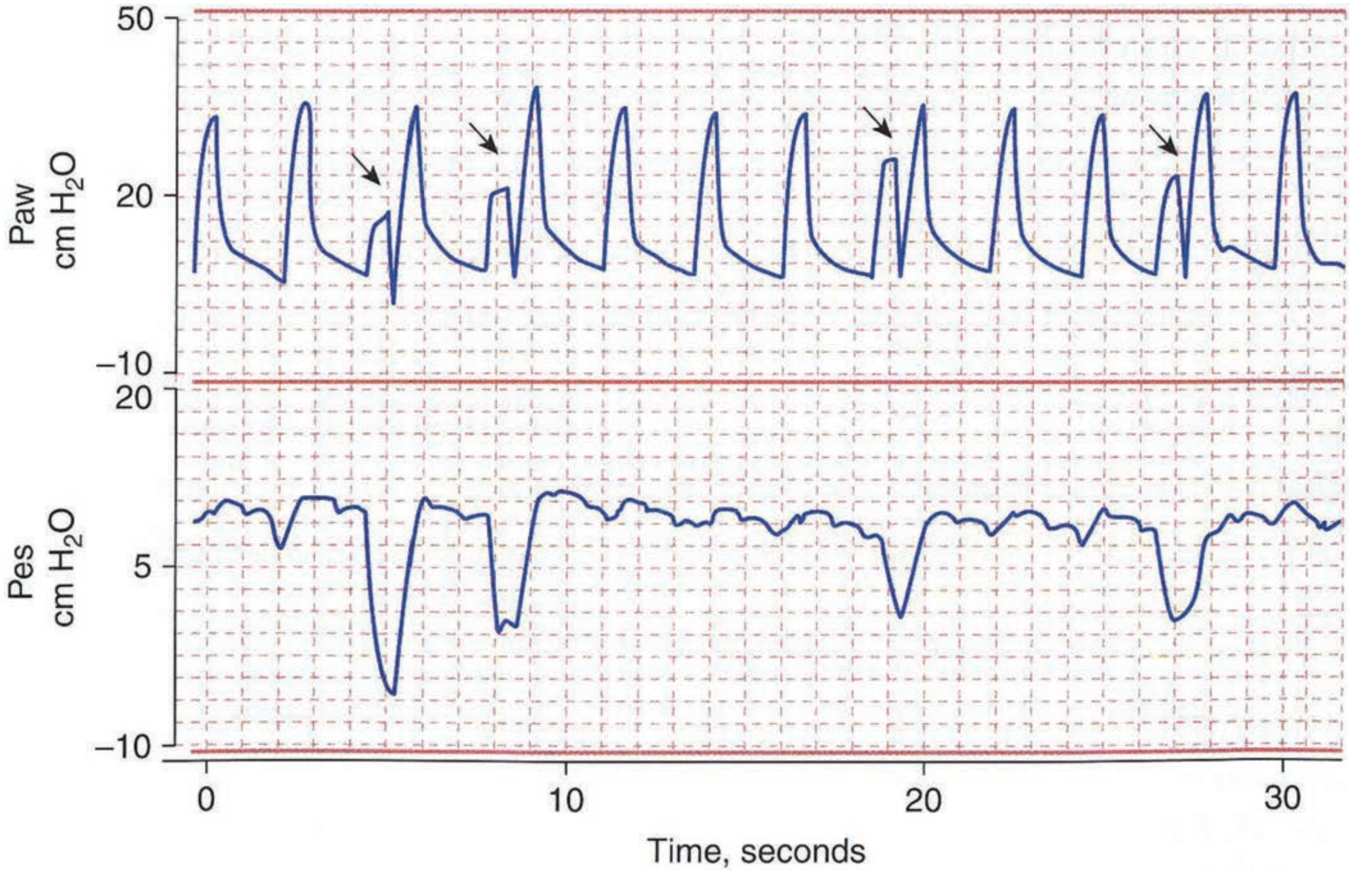

Figure 147-10 Four incidents of double triggering, each indicated by an arrowhead symbol *(↑)*. Airway pressure (Paw) and esophageal pressure (Pes) in a patient with COPD and pneumonia who was receiving assist-control ventilation at the following settings: tidal volume 600 mL, inspiratory flow 60 L/min, trigger sensitivity −2 cm H_2O, and positive end-expiratory pressure 5 cm H_2O. The duration of neural inhalation of the double-triggered breaths, roughly equivalent to the width of the associated swings in esophageal pressure, was substantially longer than the neural inhalation of the normally triggered breaths. *(Reproduced with permission from Tobin MJ, Laghi F, Jubran A. Ventilatory failure, ventilator support, and ventilator weaning. Compr Physiol. 2012;2(4):2871–2921.)*

do not relieve air hunger.[36] Neuromuscular blockers do not relieve dyspnea; indeed, they aggravate dyspnea by removing behavioral clues that alert caregivers to patient discomfort.[34]

V_T needs to be customized for each patient based on physiology and comfort. If plateau pressure is above 30 cm H_2O, it is prudent to decrease V_T to bring plateau pressure as low as possible while avoiding double triggering; a plateau pressure of less than 28 cm H_2O is a reasonable target. If plateau pressure is in the low 20s (the case for most ventilated patients), the use of unnaturally low V_T contravenes every principle of physiology.[32]

Many hospital administrators advocate the use of protocolized V_T in ventilated patients. Ungrounded in physiology, protocol advocates do not recognize that low V_T is necessarily accompanied by shortening of mechanical inspiratory time;[7] once mechanical inspiratory time becomes less than neural inspiratory time, double triggering is inevitable (Fig. 147-10). Protocol enthusiasts believe they are delivering V_T 6 mL/kg, but the patient is actually receiving 12 mL/kg—a setting proven to increase mortality.[24–26]

Respiratory Rate

Correct setting of the ventilator rate depends on the mode of ventilation employed.[21] With assist-control ventilation, the ventilator supplies a breath in response to each patient effort. With this mode, physicians commonly pay little attention to the machine rate, which may be set much lower than the patient's spontaneous rate. This gap results in two problems: (1) If the patient has a sudden decrease in respiratory center output, a low machine rate results in serious hypoventilation.[7] (2) A large discrepancy between the patient's spontaneous rate and the machine's backup rate results in a respiratory cycle with an inverse inspiratory-to-expiratory time (I:E) ratio.

Development of an inverse I:E ratio arises because inspiratory time (T_I) on the machine remains fixed at the initial setting and does not change in response to increases in the patient's spontaneous rate (Fig. 147-11).[21] For example, if the machine rate is initially set at 12

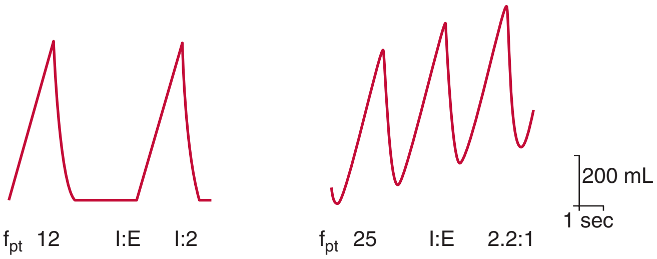

Figure 147-11 Effect of interaction between a patient's respiratory rate and the ventilator backup rate on inspiratory time–expiratory time ratio (I:E) during assist-control ventilation. Ventilator backup rate is 12 breaths/min and inspiratory time (T_I) 1.65 s. *Left panel.* If the patient's intrinsic respiratory (fpt) rate is also 12 breaths/min, the total respiratory cycle time (T_{TOT}) is 5.0 s, the expiratory time (T_E) is 3.35 s, and the I:E ratio is 1:2. *Right panel.* If the patient's respiratory rate increases to 25 breaths per minute, the new T_{TOT} is 2.4 s, T_E is 0.75 s, and I:E is 1:0.45 (or, as more conventionally noted, 2.2:1).

breaths/min (T_{TOT} of 5 s) and T_I set at 1.65 s (either set directly or indirectly as a consequence of the volume and flow settings), then expiratory time (T_E) will be 3.35 seconds. The I:E ratio will be 1:2. If the patient's spontaneous respiratory rate is increased to 25 breaths/min, T_{TOT} will be 2.4 s. Because T_I remains fixed at 1.65 s, T_E will be 0.75 s, and the I:E ratio will be 2:1. Such inverse-ratio ventilation is very uncomfortable and may lead to increased sedative use, or even to use of neuromuscular blockade, simply because of inappropriate setting of the backup rate.

Based on the above considerations, the backup rate during assist-control ventilation should be set at approximately four breaths less than the patient's spontaneous rate.[5]

■ Inspiratory Flow Rate

When patients are initially connected to a ventilator in the volume-control mode, inspiratory flow is typically set at some default value, such as 60 L/min.[5,10] Many critically ill patients have an elevated respiratory center output, and the flow setting may not be sufficient to meet the patient's flow demands. Consequently, patients will struggle against their own respiratory impedance and that of the ventilator, with consequent increase in the work of breathing.[35] This problem is usually detectable by observing a scalloped contour on the airway pressure tracing (signifying an increased level of patient work) (Fig. 147-12).[5]

Frequently, an increase in inspiratory flow will achieve a more favorable airway pressure contour (becoming more convex or outward). In some patients, however, an increase in flow causes immediate and persistent tachypnea,[37] with consequent shortening of expiratory time and increase in intrinsic positive end-expiratory pressure (PEEPi). The response to such adjustments is influenced by the Hering–Breuer reflex and is variable from patient to patient.[38]

Based on the above considerations, the clinician needs to adopt a "trial-and-error" approach, adjusting ventilator flow and observing the contour of the airway pressure tracing. No algorithm can substitute for bedside iterative adjustments.[35]

■ Fractional Inspired Oxygen Concentration (FI_{O_2})

Correction of hypoxemia is a classic goal of mechanically ventilation. Many predictive equations have been published to aid in selecting an appropriate FI_{O_2}, but none is sufficiently accurate to substitute for a trial-and-error approach.[39] Initially, FI_{O_2} is set at a high value (often 1.0) to ensure adequate oxygenation. Thereafter, the lowest FI_{O_2} that achieves satisfactory arterial oxygenation should be selected. The usual target is Pa_{O_2} 60 mm Hg or arterial saturation (Sa_{O_2}) 90%; higher values do not substantially enhance tissue oxygenation. Although it is customary to wait 30 min to assess the response to a change in FI_{O_2}, the effect is usually well defined within 10 min. When using arterial blood samples to assess oxygenation, a target of 90% for Sa_{O_2} is appropriate. If pulse oximetry is employed, an Sp_{O_2} target may result in Pa_{O_2} as low as 41 mm Hg. In white patients, a target of 92% for Sp_{O_2} indicates satisfactory oxygenation. In Black patients, however, this target may still result in significant hypoxemia.[40]

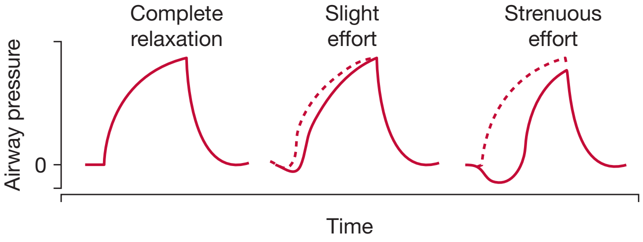

Figure 147-12 Airway-pressure waveforms recorded during assist-control ventilation. The tracings represent changes in airway pressure during inspiration in a completely relaxed patient, and in patients making slight *(center tracing)* and strenuous efforts *(tracing on right)* to breathe. The distance between the *dashed line* (representing controlled ventilation) and the *solid line* (representing spontaneous breathing) is proportional to the patient's work of breathing. *(Reproduced with permission from Tobin MJ. Mechanical ventilation. N Engl J Med. 1994;330(15):1056–1061.)*

In experimental animals, hyperoxia produces diffuse alveolar damage, with histologic changes that are indistinguishable from ARDS resulting from any other cause. No diagnostic tests distinguish oxygen-induced injury from progression of the underlying disease. Thus, the possibility of oxygen toxicity should be considered in any patient receiving an FI_{O_2} of more than 0.50 for 24 to 48 h or longer. In the face of potential oxygen toxicity, the sensible strategy is to reduce the FI_{O_2} to the lowest level compatible with adequate systemic oxygenation.

■ Positive End-expiratory Pressure

The beneficial effects of PEEP include improvement in arterial oxygenation, improvement in lung compliance, alleviation of excessive respiratory work secondary to PEEPi in patients with airflow limitation, and, possibly, a decrease in lung injury resulting from repeated alveolar collapse and reopening.[10] The principal beneficial effect of PEEP is an increase in Pa_{O_2}, which permits a decrease in FI_{O_2} and a reduction in the risk of oxygen toxicity. The major mechanism for the increase in Pa_{O_2} with PEEP is an increase in end-expiratory lung volume (Table 147-2).

Patients with ARDS develop alveolar instability and collapse. Consequently, functional residual capacity falls below closing volume, and small airways close during tidal breathing, leading to intrapulmonary shunt and hypoxemia. PEEP increases end-inspiratory lung volume by distending lung units that are already open, preventing collapse of unstable alveoli at end expiration, recruiting collapsed lung units, and redistributing liquid within the lung.[41–43] The decrease in venous admixture with PEEP is proportional to alveolar recruitment. It had been thought that the decrease in venous admixture with PEEP resulted largely from a decrease in cardiac output. This view has been shown to be erroneous.[44]

At one time PEEP was thought to decrease extravascular lung water by "pushing" alveolar fluid back into the circulation. On the contrary, PEEP can actually increase lung water.[45] As alveoli expand with application of PEEP, interstitial pressure in the extra-alveolar space decreases, leading to an increase in transmural pressure across the vessel wall. If intravascular pressures remain the same or increase, the filtration of fluid across the vessel wall increases, causing an increase in pulmonary edema; if PEEP causes a decrease in cardiac output and vascular pressures, lung water does not change. The beneficial action of PEEP in pulmonary edema is produced by redistribution of edema fluid from the alveolar space into the

TABLE 147-2 Mechanisms of Increased Pa_{O_2} with PEEP

	Redistribution of fluid within the lung
Decrease in shunt	
	Increase in end-expiratory lung volume
	Decrease in cardiac output

perivascular cuffs. This redistribution of lung water, in association with an increase in end-expiratory lung volume, is the major mechanism underlying the increase in Pa_{O_2} with PEEP.

In patients with ARDS, PEEP is often used for the purpose of recruiting previously nonfunctioning lung tissue. Selecting the right level of PEEP for a given patient is difficult because the severity of injury varies throughout the lungs. PEEP can recruit atelectatic areas, but it may also overdistend normally aerated areas.[43]

The addition of PEEP also influences lung mechanics. Patients with acute lung injury commonly have a decreased end-expiratory lung volume and, thus, tidal breathing occurs on the low, flat portion of the pressure–volume curve (Fig. 147-13). By shifting tidal breathing to a more compliant portion of the curve, PEEP may reduce the work of breathing.[46] In patients with an airflow limitation and PEEPi who have difficulty triggering the ventilator, the addition of external PEEP (to a level not exceeding the level of PEEPi) can help to counteract this problem, because to trigger the ventilator the alveolar pressure needs to be decreased only below the level of external PEEP, rather than below zero.[47] In addition to the injury induced by high inflation pressures, mechanical ventilation at a low end-expiratory lung volume aggravates lung injury in laboratory animals, possibly because of shear stresses associated with the repeated closing and opening of alveolar units.[48]

Overall, about 30% of patients with acute lung injury either do not benefit from PEEP or experience a fall in Pa_{O_2}.[49,50] With the patient in the supine posture, PEEP generally recruits the regions of the lung closest to the apex and sternum. Conversely, PEEP can increase the amount of nonaerated tissue in the regions close to the spine and diaphragm. Among patients in the early stages of ARDS, those with pulmonary causes, such as pneumonia, are less likely to benefit from PEEP than patients with nonpulmonary causes, such as intra-abdominal sepsis or extrathoracic trauma.[51] This distinction may be related to the type of morphologic involvement: Pulmonary causes of ARDS are characterized by alveolar filling, whereas nonpulmonary causes are characterized by interstitial edema and alveolar collapse. In the later stages of ARDS, remodeling and fibrosis may eliminate this distinction between pulmonary and nonpulmonary causes.

Three randomized trials on the effect of PEEP on survival in patients with ARDS have been undertaken: the ALVEOLI trial, the LOV trial, and the Express trial.[52–54] The results of all three trials revealed no improvement in patient survival. The ALVEOLI investigators employed a complex sliding scale for adjusting PEEP and FI_{O_2}.[52] When patients were receiving FI_{O_2} 0.60, the design mandated that patients receive either PEEP 10 or 20 cm H_2O, with no other options. At FI_{O_2} 0.80, patients were mandated to receive either PEEP 14 or 22 cm H_2O, with no other options. Such a nonscientific design robs the ALVEOLI trial of any clinical relevance. The investigators of the LOV trial employed the exact same flawed PEEP-FI_{O_2} table,[53] again depriving the LOV trial of any scientific credibility.

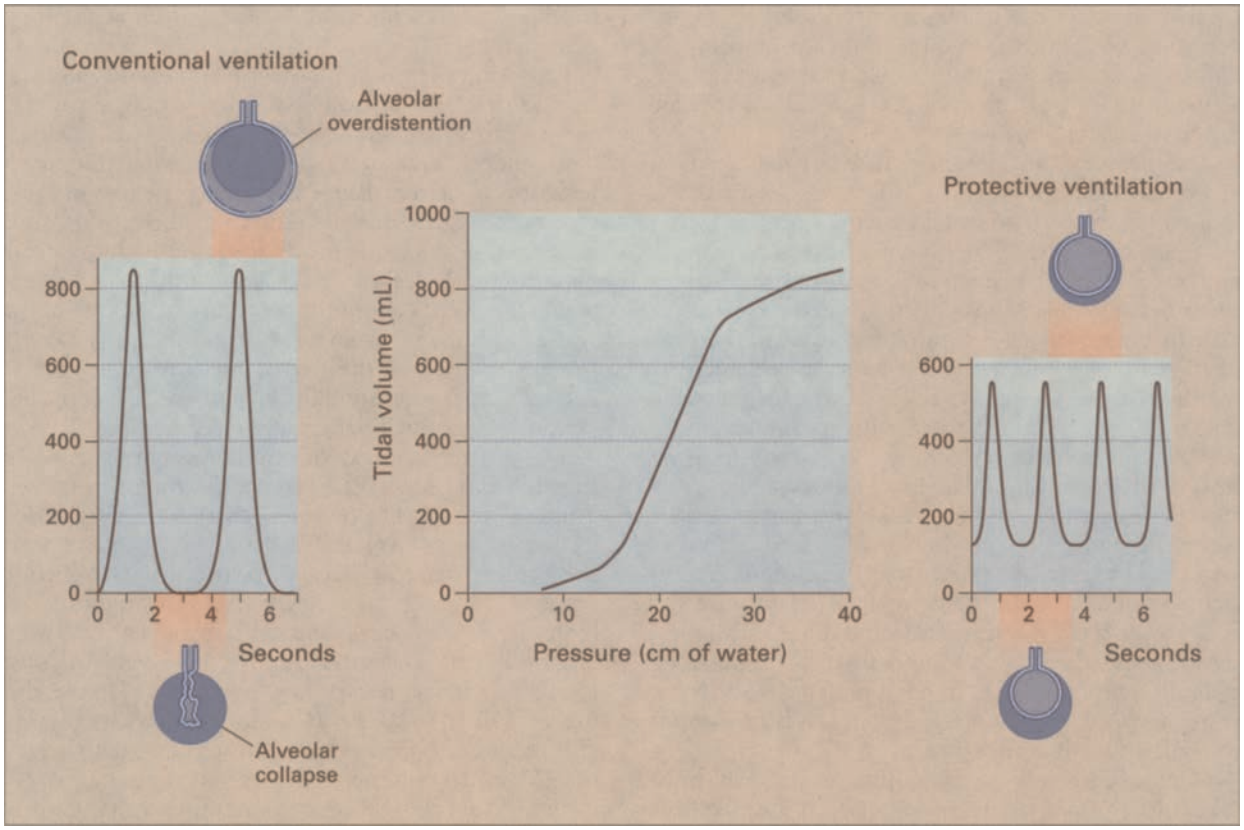

Figure 147-13 Respiratory pressure–volume curve and the effects of traditional versus protective ventilation in a 70-kg patient with acute respiratory distress syndrome. The lower and upper inflection points of the inspiratory pressure–volume curve *(center panel)* are at 14 and 26 cm H_2O, respectively. With conventional ventilation at a tidal volume of 12 mL/kg and zero end-expiratory pressure *(left panel)*, alveoli collapse at the end of expiration. The generation of shear forces during the subsequent mechanical inflation may tear the alveolar lining, and attaining an end-inspiratory volume higher than the upper inflection point causes alveolar overdistention. With protective ventilation at a tidal volume of 6 mL/kg (*right panel*), the end-inspiratory volume remains below the upper inflection point; the addition of PEEP at 2 cm H_2O above the lower inflection point may prevent alveolar collapse at the end of expiration and provide protection against the development of shear forces during mechanical inflation. *(Reproduced with permission from Tobin MJ. Advances in mechanical ventilation. N Engl J Med. 2001;344(26):1986–1996.)*

It is long recognized that the response to PEEP is very variable in ARDS. Some patients develop overdistention with PEEP 10 cm H_2O, whereas other patients show little aeration despite airway pressure of 45 cm H_2O.[43] The investigators made no attempt to determine the individual characteristics of patients; instead, every patient was treated the same in each arm of the trial.[52–54]

Talmor et al.[55] hypothesized that setting PEEP based on transpulmonary pressure might achieve a better physiologic result. They randomized 61 patients with acute lung injury or ARDS to two study arms, one where PEEP was adjusted to maintain a transpulmonary pressure between 0 and 10 cm H_2O at end expiration; in the second arm, PEEP was adjusted according to airway pressure. A trend, although not statistically significant, toward lower mortality at 28 days was observed in the esophageal catheter group. When estimating absolute pleural pressure, Talmor et al.[55] employed a correction factor of 5 cm H_2O in all patients, which constitutes a major assumption. The advantage of setting PEEP based on transpulmonary pressure has not been replicated or adopted.

BRONCHODILATOR THERAPY

Several obstacles are encountered when inhaled drugs are administered to ventilated patients. As a result, drug deposition to the lower respiratory tract is less than that in ambulatory patients. Determinants of aerosol deposition include the configuration of the endotracheal tube and ventilator circuit, ventilator mode and settings, and patient-related factors.[56]

Nebulizers have been used traditionally for the delivery of bronchodilators, but they have a number of disadvantages.[56] Nebulizer contamination causes aerosolization of bacteria, and lack of attention to this matter by healthcare providers has led to epidemics of nosocomial pneumonia.

Tidal volume and inspiratory flow must be adjusted to compensate for nebulizer flow. This factor is inconsequential in most adults, but instances of hypoventilation have occurred in patients who are unable to trigger the ventilator. Another shortcoming of nebulizers is the considerable variation in efficiency of different commercial brands, as well as among various batches of the same brand.

In contrast, metered-dose inhalers (MDIs) are easy to administer, involve less personnel time, and provide reliable dosing. Moreover, when MDIs are used with a collapsible cylindrical spacer, it is not necessary to disconnect the ventilator circuit for each treatment. Thus, risk of ventilator-associated pneumonia is decreased. Using MDIs instead of nebulizers results in substantial cost savings. The combination of an MDI and a chamber device achieves a four- to sixfold greater delivery of aerosol than MDI actuation into a connector attached directly to the endotracheal tube or into an inline device that lacks a chamber.[56] Delivery is increased with use of a higher V_T and longer fractional inspiratory time (T_I/T_{TOT}). Aerosol delivery is decreased by a high inspiratory flow rate; heating and humidification of inhaled gas reduce aerosol deposition by about 40%. When an aerosol is carried by a low-density gas, such as an 80:20 helium–oxygen mixture, aerosol delivery from an MDI is increased by more than 50%.

A dose–response study of 4, 8, and 16 puffs of albuterol (administered with an MDI and cylindrical spacer) conducted in ventilated patients with COPD (Fig. 147-14) demonstrated a decrease in airway resistance after 4 puffs of albuterol; no additional effects were noted after cumulative doses of 12 and 28 puffs.[57] In another study in ventilated patients with COPD, the bronchodilator effect of a single dose of 4 puffs of albuterol was sustained for at least 60 min. The bronchodilator effect obtained with 4 puffs of albuterol from an MDI was comparable with that obtained with 6 to 12 times the same dose given by a nebulizer.

Steps to achieve maximum bronchodilator effect with use of MDIs in ventilated patients are listed in Table 147-3.[56] Therapy

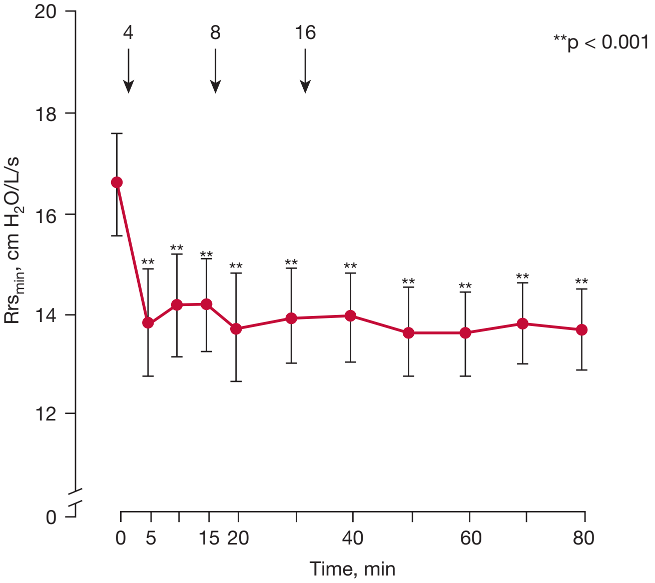

Figure 147-14 Effect of albuterol on minimal inspiratory resistance (Rrsmin) in 12 stable mechanically ventilated patients with chronic obstructive pulmonary disease. Significant decreases in resistance occurred within 5 min of administration of 4 puffs of albuterol. The addition of 8 and 16 puffs (cumulative doses of 12 and 28 puffs, respectively) did not achieve a significantly greater effect than that with 4 puffs ($p > 0.05$). *Bars* represent SE. **$p < 0.001$. *(Modifed with permission from Dhand R, Duarte AG, Jubran A, et al. Dose-response to bronchodilator delivered by metered-dose inhaler in ventilator-supported patients. Am J Respir Crit Care Med. 1996;154(2 Pt 1):388–393.)*

TABLE 147-3 Technique for Using Metered-Dose Inhalers in Mechanically Ventilated Patients

1. Assure $V_T > 500$ mL (in adults) during assisted ventilation
2. Aim for an inspiratory time (excluding the inspiratory pause) >0.30 of total breath duration
3. Ensure that the ventilator breath is synchronized with the patient's inspiration
4. Shake the metered-dose inhalers vigorously
5. Place canister in actuator of a cylindrical spacer situated in inspiratory limb of ventilator circuit[a]
6. Actuate metered-dose inhalers to synchronize with precise onset of inspiration by the ventilator[b]
7. Allow a breath hold at end-inspiration for 3–5 s
8. Allow passive exhalation
9. Repeat actuations after 20–30 s until total dose is delivered[c]

[a] *With metered-dose inhalers, it is preferable to use a spacer that remains in the ventilator circuit to avoid disconnecting the ventilator circuit for each bronchodilator treatment. Although bypassing the humidifier can increase aerosol delivery, it prolongs each treatment and requires disconnecting the ventilator circuit.*

[b] *In ambulatory patients with metered-dose inhalers placed inside the mouth, actuation is recommended briefly after initiation of inspiratory airflow. In mechanically ventilated patients using a metered-dose inhaler and spacer combination, actuation should be synchronized with onset of inspiration.*

[c] *The manufacturer recommends repeating the dose after 1 min. Metered-dose inhalers' actuation within 20–30 s after the previous dose does not compromise drug delivery.*

Modified with permission from Dhand R, Tobin MJ. Inhaled bronchodilator therapy in mechanically ventilated patients. Am J Respir Crit Care Med. 1997;156(1):3–10.

may be given in combination with either controlled or assisted ventilation, provided aerosol administration is synchronized with inspiratory flow. Based on the recommended technique for use of an MDI in ambulatory patients, some authors recommend use of a post-inspiratory breath hold; with optimal technique, however, this maneuver does not influence bronchodilator response in ventilated patients. Although humidification of the circuit reduces aerosol deposition, it is advisable not to bypass the humidifier. Even with a humidified circuit, significant bronchodilation can be achieved with as few as four puffs of a bronchodilator aerosol when the MDI technique is carefully executed.

MONITORING AND COMPLICATIONS

Several devices can be used to monitor pulmonary gas exchange, respiratory neuromuscular function, respiratory mechanics, and patient–ventilator interaction. Use of the derived information permits the physician to better tailor ventilator settings to an individual patient's physiologic characteristics, with the intent of enhancing patient comfort.[58] Monitoring of key variables helps to minimize the risk of iatrogenic complications and alerts the physician to the likelihood of an impending catastrophe, allowing sufficient time for the institution of lifesaving measures.

Patients receiving mechanical ventilation are at risk of numerous complications, including oxygen toxicity, volutrauma, air leaks, decreased cardiac output, and endotracheal tube–related problems.

WEANING

The term *weaning* literally means a slow, gradual decrease in the amount of ventilator support. The term, however, is used more commonly to refer to all methods of discontinuing mechanical ventilation.[59]

Causes of Weaning Failure

After discontinuation of mechanical ventilation, up to 25% of patients experience respiratory distress severe enough to necessitate the reinstitution of ventilator support. Among patients who cannot be weaned, disconnection from the ventilator is followed almost immediately by an increase in respiratory frequency and fall in tidal volume—that is, rapid, shallow breathing (Fig. 147-15).[60] As a trial of spontaneous breathing is continued over the next 30 to 60 min, respiratory effort increases considerably, reaching more than four times the normal value at the end of this period (Fig. 147-16).[61] The increased effort is caused mainly by worsening respiratory mechanics.[62] Respiratory resistance increases progressively, reaching about seven times the normal value at the end of a failed weaning trial; lung stiffness also increases, reaching five times the normal value; and gas trapping, measured as PEEPi, more than doubles over the course of the trial.[61] Before weaning is started, however, respiratory mechanics in such patients are similar to patients in whom subsequent weaning is successful. Thus, unknown mechanisms associated with the act of spontaneous breathing cause the worsening of respiratory mechanics in patients who are weaning failures.

In addition to the increase in respiratory effort, an unsuccessful attempt at spontaneous breathing causes considerable cardiovascular stress. Patients may experience substantial increases in right- and left-ventricular afterload during a trial of spontaneous breathing, with increases of 39% and 27% in pulmonary and systemic arterial pressures, respectively.[63] The changes are most likely attributable to the extreme negative swings in intrathoracic pressure. At the completion of a weaning trial, the level of oxygen consumption is equivalent in patients who can be weaned and in those who cannot. How the cardiovascular system meets the oxygen demand differs in the two groups of patients.

In patients who are successfully weaned, oxygen demand is met through an increase in oxygen delivery, mediated by the expected increase in cardiac output on discontinuation of positive-pressure ventilation. In patients who cannot be weaned, oxygen demand is met through an increase in oxygen extraction; these patients have a relative decrease in oxygen delivery. The greater oxygen extraction causes a substantial decrease in mixed venous oxygen saturation, contributing to the arterial hypoxemia that occurs in some patients.[63]

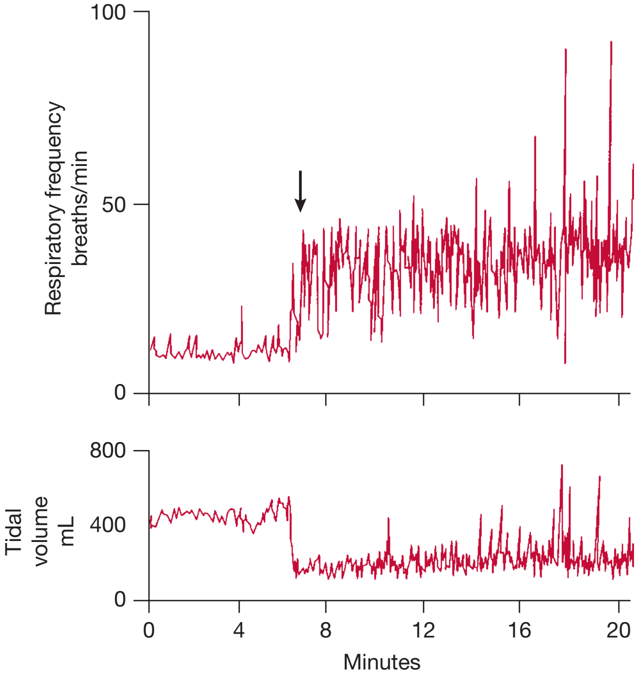

Figure 147-15 A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The *arrow* indicates the point of resuming spontaneous breathing. Rapid, shallow breathing developed almost immediately after discontinuation of the ventilator. *(Reproduced with permission from Tobin MJ, Perez W, Guenther SM, et al. The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. Am Rev Respir Dis. 1986;134(6):1111–1118.)*

Over the course of a trial of spontaneous breathing, about half of the patients in whom the trial fails have an increase in Pa_{CO_2} of 10 mm Hg or more. The hypercapnia is not usually a consequence of a decrease in minute ventilation. Instead, hypercapnia results from rapid, shallow breathing, which causes an increase in dead-space ventilation.[60] In a small proportion of patients who cannot be weaned, primary depression of respiratory center output may be responsible for the hypercapnia.

Timing of the Weaning Process

One of the major challenges in the management of ventilator-supported patients is deciding on the right time to discontinue mechanical ventilation. If the physician is too conservative and postpones weaning onset, the patient is placed at an increased risk of life-threatening, ventilator-induced complications. Conversely, if weaning is begun prematurely, the patient may suffer cardiopulmonary or psychological decompensation of sufficient severity to set back a patient's clinical course.[59]

In randomized trials of different weaning techniques, most patients who had received mechanical ventilation for a week or longer were able to tolerate ventilator discontinuation on the first day that weaning-predictor tests were measured.[64,65] Many of these patients would have tolerated extubation a day or so earlier. As such, one of the main sources of weaning delay is the failure of the physician to *think* that the patient *just might* come off the ventilator. Psychological research suggests that much of this delay in ventilator weaning results from clinicians being overconfident in their intuition

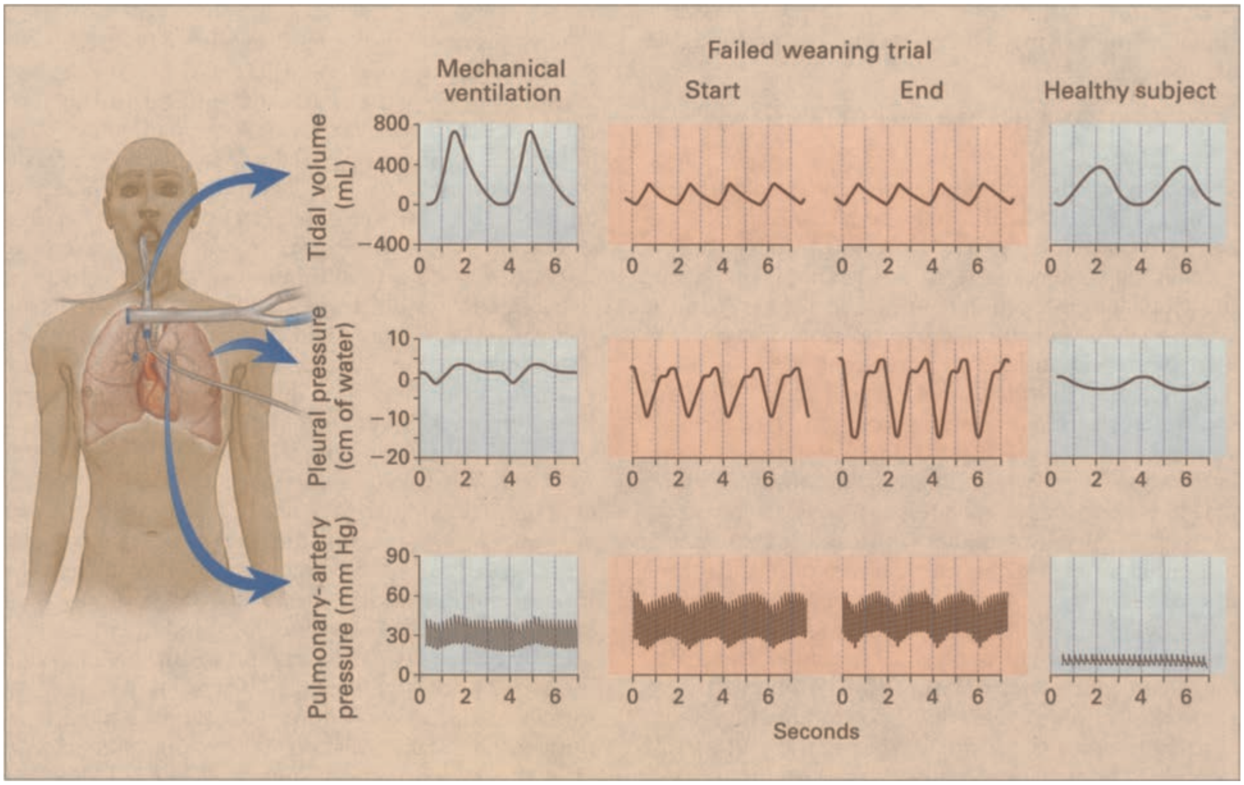

Figure 147-16 Tidal volume, pleural pressure, and pulmonary-artery pressure during assist-control ventilation and at the start and end of a failed weaning trial. During mechanical ventilation, the patient's inspiratory effort is in the normal range, and the pulmonary-artery pressure is 45/22 mm Hg. At the start of the weaning trial, tidal volume falls to 200 mL, respiratory frequency increases to 33 breaths per minute, and a swing of 11 cm H_2O in pleural pressure is noted; the pulmonary-artery pressure at the end of expiration is 60/28 mm Hg. At the end of the trial, 45 min later, the tidal volume and respiratory frequency are unchanged, a swing in pleural pressure of 19 cm H_2O is evident, and PEEPi is 4 cm H_2O; pulmonary artery pressure is 60/31 mm Hg. The values in a healthy subject are tidal volume, 380 mL; respiratory frequency, 17 breaths per minute; pleural-pressure swing, 3 cm H_2O; and pulmonary artery pressure, 18/8 mm Hg. *(Reproduced with permission from Tobin MJ. Advances in mechanical ventilation. N Engl J Med. 2001;344(26):1986–1996. Data from Tobin MJ, Perez W, Guenther SM, et al. that a patient is not ready for a weaning trial.[59] Another source of error is the failure of clinicians to pay close attention to pretest probability—they fail to recognize the importance of Bayesian principles in clinical decision-making. When taking care of a ventilator-supported patient, physicians should be mindful of these cognitive processes and employ compensatory tactics, specifically the use of screening tests, to spot a patient's readiness for weaning. By alerting an unsuspecting physician to a patient's readiness to tolerate unassisted ventilation—hours or days before he or she would otherwise order a spontaneous breathing trial—weaning-predictor tests circumvent the cognitive errors inherent in clinical decision-making.[59]

Physicians commonly view diagnostic testing in monolithic terms: a test is a test is a test. In reality, diagnostic testing has to satisfy two very different tasks: one is screening, the other is confirmation.[66] The characteristics of these test types differ, and a single diagnostic test rarely fulfills both functions.[66]

The fundamental job of a weaning-predictor test is screening. Because the goal is to not miss anyone with the condition under consideration, a good screening test has a very low rate of false-negative results; to achieve this goal, a higher false-positive rate is acceptable. Thus, an ideal screening test has a very high sensitivity. The ratio of respiratory frequency to tidal volume (f/V_T) meets this requirement; numerous studies have documented that its sensitivity is 0.90 or higher.[67,68]

The f/V_T ratio must be calculated during spontaneous breathing. Measurements of f/V_T in the presence of pressure support or CPAP will result in inaccurate predictions of weaning outcome.[59] The higher the f/V_T ratio, the more rapid and shallow the breathing and the greater the likelihood of unsuccessful weaning. A ratio of 100 discriminates between successful (<100) and unsuccessful (>100) attempts at weaning.[67]

Because the results of screening tests are often negative, an ideal screening test should be simple, expeditious, and safe.[66] Measurement of f/V_T takes a minute or so to perform. In contrast, a trial of spontaneous breathing takes 0.5 to 2 h to perform, during which time attendants commonly leave the patient's room. Accordingly, a spontaneous breathing trial does not satisfy the criteria for a desirable screening test, and commencing weaning with such a trial is likely to prolong the weaning process.[59]

If clinicians obtain weaning-predictor tests at the earliest point that a patient might tolerate extubation, the results will be negative at least half the time. In studies of weaning-predictor tests, however, positive results have been obtained at least 75% of time.[68] Such a high rate of positive test results indicates that clinicians were being too slow in initiating the weaning process.

When a screening test is positive, the diagnostician proceeds to a confirmatory test.[66] A positive confirmatory test result essentially rules in a condition: the likelihood of a patient tolerating a trial of extubation is very high. An ideal confirmatory test has a very low rate of false-positive results, that is, a high specificity. The specificity of a weaning trial is not known and will never be known because its determination would involve an unethical experiment—extubating all patients who fail a weaning trial and counting how many are reintubated.[59]

Weaning Trials

Four methods can be used for conducting a weaning trial. The oldest is to perform trials of spontaneous breathing several times a day, using a T-tube circuit that contains an enriched supply of oxygen.[59] Initially, 5 to 10 min in duration, T-tube trials are extended and repeated several times a day until the patient can sustain spontaneous ventilation for several hours. This approach has become unpopular because it involves considerable time on the part of ICU staff.

For many years, IMV was the most popular methods of weaning.[59] With IMV, the mandatory rate from the ventilator is reduced in steps of 1 to 2 breaths/min, and an arterial blood gas is obtained about 30 min after each rate change.[16] Unfortunately, titrating the number of breaths from the ventilator in accordance with the results of arterial blood gases can produce a false sense of security. As few as two to three positive-pressure breaths per minute can achieve acceptable blood gases, but these values provide no information regarding the patient's work of breathing (which may be excessive). At IMV rates of 14 breaths/min or less, patient inspiratory efforts are increased to a level likely to cause respiratory muscle fatigue.[17,18] Moreover, this occurs not only with the intervening spontaneous breaths, but also with ventilator-assisted breaths. Consequently, use of IMV may actually contribute to the development of respiratory muscle fatigue or prevent its recovery.

When pressure support is used for weaning, the level of pressure is reduced gradually (decrements of 3–6 cm H_2O) and titrated based on the patient's respiratory frequency.[19,64] When the patient tolerates a minimal level of pressure support, he or she is extubated. What exactly constitutes a "minimal level of pressure support" has never been defined.[20]

The fourth method of weaning is to perform a single, daily T-tube trial, lasting for 30 to 120 min.[59,65] If this trial is successful, the patient is extubated. If the trial is unsuccessful, the patient is given at least 24 h of respiratory muscle rest with full ventilator support before another trial is performed.[62]

Two randomized trials have revealed that weaning time was three times longer with IMV than it was with the use of T-tube trials.[64,65] In a study involving patients with respiratory difficulties on attempted weaning, T-tube trials halved the weaning time as compared with pressure support;[65] in another study, the weaning time was similar with the two methods.[64] Performing trials of spontaneous breathing once a day is as effective as performing such trials several times a day, but much simpler.[65] In patients not expecting to pose any particular difficulty with weaning, a half-hour trial of spontaneous breathing is as effective as a 2-h trial.[69] In a study of patients receiving prolonged mechanical ventilation at a long-term acute care hospital, the rate of successful weaning was more than 40% higher with trials involving unassisted breathing through a tracheostomy than with use of pressure support.[70]

In conclusion, to minimize the likelihood of either delayed weaning or premature extubation, a two-step diagnostic strategy is recommended: measurement of weaning predictors followed by a weaning trial. The critical step is for the physician to contemplate the possibility that a patient just might be able to tolerate weaning. Such diagnostic triggering is facilitated through use of a screening test, which is the rationale for measurement of weaning-predictor tests. It is important not to postpone this first step by waiting for a more complex diagnostic test, such as a T-tube trial.

EXTUBATION

Decisions about weaning and extubation are commonly conflated. When a patient tolerates a weaning trial without distress, a clinician feels reasonably confident that the patient will be able to sustain spontaneous ventilation after extubation. Before removing the endotracheal tube, however, the clinician also has to judge whether the patient will be able to maintain a patent upper airway after extubation.[59,71]

Among patients who are expected to tolerate extubation without difficulty, about 10% to 20% fail and are reintubated.[64] Mortality among reintubated patients is more than six times as high as mortality among patients who tolerate extubation.[69] The reason for the higher mortality is unknown. It might be related to the development of new problems after extubation or complications associated with reinsertion of a new tube. A more likely explanation is that the need for reintubation reflects greater severity of the underlying illness.[71]

Because of the high mortality associated with reintubation, clinicians are eager to avoid this problem. The major diagnostic test used to predict the success of an extubation attempt is a weaning trial. In contrast to the many studies that have evaluated the reliability of diagnostic tests that predict the outcome of a trial of weaning, the diagnostic accuracy of weaning trials in predicting the outcome of a trial of extubation is unknown. Moreover, the accuracy is impossible to determine because the experiments necessary to measure the sensitivity and specificity of a weaning trial (for predicting extubation outcome) are unethical.

Many physicians find it convenient to extubate a patient once he or she can breathe comfortably on a pressure support of about 7 cm H_2O and PEEP 5 cm H_2O based on the belief that such "minimal ventilator settings" are simply overcoming the resistance engendered by an endotracheal tube.[72] This claim ignores the inflammation and edema that develops in the upper airways after an endotracheal tube has been in place for a day or more. On removal of the tube, the mucosal swelling produces an increase in upper airway resistance.

Straus et al.[73] demonstrated experimentally that the respiratory work dissipated against the supraglottic airway after extubation is almost identical to the work dissipated against an endotracheal tube before extubation. Thus, applying any level of pressure support causes physicians to underestimate the respiratory resistance a patient will encounter after extubation.

The addition of a small amount of pressure support produces surprisingly large reductions in inspiratory work in ventilated patients: 5 cm H_2O decreases inspiratory work by 31% to 38%, and 10 cm H_2O decreases work by 46% to 60%.[20,74] Independently, addition of 5 cm H_2O of PEEP can decrease work of breathing by as much as 40% in ventilated patients.[74] In the case of a patient who might experience cardiorespiratory difficulties after extubation, it is incumbent on a physician to ensure that the patient is able to breathe comfortably for about 30 minutes in the complete absence of pressure support or PEEP before removal of the endotracheal tube.[72]

CONCLUSION

Although the ventilator is a machine, the greatest challenge in its operation is cognitive, not technical. This distinction was highlighted during the COVID-19 pandemic. A generation of physicians nurtured on protocols and guidelines were left in the lurch when they faced an onslaught of patients requiring decisions based on clinical judgment. Employing protocols that cautioned against noninvasive strategies and advocated liberal use of intubation contributed to the high mortality of COVID-19 patients in many hospitals. No algorithm can substitute for trial and error (also known as the scientific method: hypothesis and experimentation), interpreting the patient's response in a physiologic framework, and making iterative adjustments.

CHAPTER 148

Principles of Noninvasive Pressure-targeted Ventilation

Bernardo Selim
Janet Hilbert
Henry K. Yaggi

INTRODUCTION

Emergent technologies have provided a wide variety of noninvasive ventilation (NIV) devices and modes to deliver treatment for respiratory failure through a mask or tracheotomy, both in the acute care setting and at home. An in-depth understanding of NIV indications, modes, and settings is crucial to guarantee delivery of effective therapy. However, knowledge gaps exist in most practitioners regarding matching advanced NIV modes and settings to a patient's unique respiratory failure pathophysiology. In this chapter we review the principles of NIV devices and modes, assess indications for its use (e.g., neuromuscular and chest wall disease, obstructive airway diseases, obesity-related respiratory failure), and review the most recent published literature, including guidelines in the application (and adjustment) of these devices during hospitalization and at home. For additional information, the reader is referred to Chapters 98, 99, and 142, in which the use of noninvasive ventilation in management of sleep-disordered breathing and the pathogenesis of hypoventilatory disorders are discussed.

PRINCIPLES OF PRESSURE-TARGETED NONINVASIVE VENTILATION

Before considering the details of a noninvasive mechanical ventilator circuit and important underlying physiologic principles, we provide a brief review of the history of the modality.

Brief Historic Perspective of Noninvasive Positive Airway Pressure Modes

In 1981, Sullivan published his seminal paper describing a novel therapeutic modality to successfully treat obstructive sleep apnea (OSA). By applying a mask ("soft plastic tubes shaped to fit each naris"), hoses, and a "vacuum cleaner–blower motor with variable speed control," he was able to deliver pressurized air to a patient's upper airway. He coined the term *continuous positive airway pressure* (CPAP) to describe the delivery of constant pressure throughout the respiratory cycle.[1] Today, CPAP is a commonly prescribed noninvasive positive airway pressure mode that provides a pneumatic splint to the pharyngeal airway (preventing it from collapsing during sleep), along with improvement in end-expiratory lung volumes and oxygenation (improvement of ventilation–perfusion matching). However, by providing the same single (constant) pressure during inhalation and exhalation, CPAP does not support or augment a patient's tidal volume and, therefore, minute ventilation (Fig. 148-1A).

Nomenclature of Noninvasive Positive Airway Pressure (PAP) Therapy

Continuous positive airway pressure (CPAP)	
Non-invasive Ventilation (NIV) *(Bilevel Positive Airway Pressure Modes)*	• Bilevel PAP devices (BPAP-S or BPAP-ST) • Volume Assured Pressure Support (VAPS) • Adaptive Servo Ventilation (ASV)

Figure 148-1 Differences between CPAP and NIV in respiratory support. **A.** CPAP versus NIV in respiratory support. **B.** Types of positive airway pressure modes: BPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; FRC, functional residual capacity; NIV, noninvasive ventilation; RR, respiration rate; ST, spontaneous-timed; UA, upper airway; Vt, tidal volume.

In 1990, almost 10 years after the introduction of CPAP, Sanders and Kern published a novel research article describing the treatment of OSA by "independently adjusted inspiratory and expiratory positive airway pressures" via a nasal mask.[2] By installing a flow sensor (input), the device was able to correctly detect (and differentiate) the patient's breath phase to deliver a different therapeutic pressure during inhalation—inspiratory positive airway pressure (IPAP)—and during exhalation—expiratory positive airway pressure (EPAP). This research introduced for the first time the principles of bilevel positive airway pressure ventilation (BPAP). With the introduction of digital algorithmic analysis of the flow signal (input), advanced bilevel devices have developed the capability to self-modulate IPAP and/or EPAP as well as to "time" the initiation (trigger) and/or termination (cycle) of each breath. Different from CPAP, these advanced modes of BPAP, collectively known as *noninvasive ventilation* (NIV), have been applied either invasively through a tracheotomy tube or noninvasively via a mask for long-term management of patients with respiratory failure in need of minute ventilation augmentation and/or muscle load reduction (Fig. 148-1A,B).

Pathophysiology: Decision Framework in Selecting NIV Modes

A practical approach to NIV selection is based on analysis of arterial blood gases.

Respiratory Failure Related to CO_2 Imbalance

Respiratory failure encompasses a heterogeneous group of breathing disorders with diverse pathophysiologic mechanisms, impacting carbon dioxide (CO_2) balance, oxygenation levels, or both (Table 148-1).

In practical terms, respiratory failure associated primarily with changes in CO_2 balance may be divided into two main groups as reflected in arterial carbon dioxide tension (Pa_{CO_2}) obtained by arterial blood gas (ABG). In one group, alveolar hypoventilation disorders ("pump failure") are associated with hypercapnia (Pa_{CO_2} $\geq$45 mm Hg) as a result of increased respiratory system load (chest wall and lung loads, e.g., kyphoscoliosis or chronic obstructive pulmonary disease), decreased respiratory drive (ventilation control abnormalities, e.g., opioid overdose), and/or inadequate respiratory muscle strength/endurance (e.g., neuromuscular disorders), or a combination of them (Fig. 148-2A,B).

In contrast, the Central Sleep Apnea Syndrome (CSAS) group consists of eucapnic (Pa_{CO_2} $\leq$45 mm Hg) or even hypocapnic (Pa_{CO_2} <40 mm Hg) breathing disorders characterized by intermittent reduction (or absence) of respiratory efforts (e.g., heart failure–related Cheyne–Stokes respiration [CSR]). CSAS is most often the result of unstable breathing caused by high loop gain. Loop gain is an engineering term that describes in pulmonary physiology the degree of response, in this case, of the respiratory control system, after a ventilatory disturbance results in minimal changes of nocturnal Pa_{CO_2}.[3] The higher the loop gain, the higher the respiratory instability. Loop gain has three components: circulatory time, plant gain, and controller gain. The prolonged lung-to-brain circulatory delay is commonly seen in heart failure (HF) due to reduced cardiac output. In HF, the circulatory delay is doubled (10–20 s). Controller gain is related to chemosensitivity

TABLE 148-1 Pathophysiology of Hypoventilation Disorders and Central Sleep Apnea Syndromes

Pathophysiology	Disorders	Notes
High Arterial Carbon Dioxide Tension ***(Alveolar Hypoventilation Disorders)***	*Ventilatory control abnormalities:* • E.g., congenital or acquired central alveolar hypoventilation	Ventilatory control is affected by mutations in the PHOX2B gene (congenital central alveolar hypoventilation syndrome) or secondary (acquired) compromise of the hindbrain (brainstem and cerebellum) by infections, autoimmune diseases, or paraneoplastic syndromes
	Neuromuscular disorders: • E.g., amyotrophic lateral sclerosis (ALS)	Inability to translate ventilatory center output into appropriate output by the neuromuscular apparatus, thus rendering ventilatory control ineffective
	Chest wall abnormalities: • E.g., kyphoscoliosis or obesity hypoventilation syndrome (OHS)	Increased work of breathing and limited lung expansion due to thoracic cage abnormalities, such as skeletal rigidity or excessive load from adipose tissue, blunts the intended response to CO_2
	Lung disorders: • E.g., chronic obstructive pulmonary disease (COPD)	Mechanical effectiveness of ventilation is compromised by ventilation–perfusion inequality, respiratory muscle dysfunction, and changes in chemosensitivity of the respiratory centers; during sleep, ventilation failure is particularly evident in REM sleep, when persistence of ventilation is primarily dependent on diaphragm activity and central (nonmetabolic) respiratory drive
Normal or Reduced Carbon Dioxide Tension ***(Central Sleep Apnea Syndromes)***	*Treatment-emergent central sleep apnea*	High loop gain induced by CPAP therapy for obstructive sleep apnea syndrome; OSA phenotype characterized by ventilatory control center instability in response to minor CO_2 fluctuations induced by CPAP therapy
	Central sleep apnea with Cheyne–Stokes respiration	Primarily seen in patients with congestive heart failure with reduced or preserved ejection fraction; high loop gain with feedback delays induced by poor cardiac output; patients exhibit enhanced ventilatory drive leading to cyclic over- and undershoot of ventilation (crescendo and decrescendo breathing pattern interspaced by central apneic events)
	Central sleep apnea due to high-altitude periodic breathing	High loop gain–induced CSA by hypoxemia as a result of decreased fractional oxygen concentration at high altitude
	Central sleep apnea due to medications or substances: • E.g., opioids	Loop gain is variable, and opioid effects on the pre-Bötzinger complex (respiratory rhythm generator) result in reduction of respiratory rate

Figure 148-2 Pathophysiology of respiratory failure. **A.** Etiology of respiratory failure. **B.** Alveolar hypoventilation. **C.** Campbell diagram with representation of work of breathing (WOB). Work of breathing is the result of delta volume (tidal volume, Vt) × pressure from muscle contraction (Pmus) needed to overcome the respiratory load from the respiratory system (equation of motion defined by compliance, resistance, and intrinsic positive end-expiratory pressure (PEEPi). Pmus is the pressure change generated by contraction of inspiratory muscles (shown by the length of the *horizontal arrow*). The *diagonally hatched area* is work done against resistance, and the *stippled area* is work done against elastance of lung and chest wall. Work of breathing is the summation of static work (energy required to maintain volume) and dynamic work (energy necessary to keep flow and overcome resistance). **D.** Transmural pressures. The transmural pressure (Tm) is equal to the luminal pressure (Pl) − surface pressure (Ps). This relationship defines the working pressure of the heart chambers and blood vessels within the intrathoracic cavity. The same principle applies for the transpulmonary pressures (alveolar pressure minus pleural pressure) that define the lung volumes and the perialveolar capillary vascular resistance. CO_2, carbon dioxide; E, elastance; LV, left ventricle; PA, pulmonary artery; PEEPi, intrinsic positive end expiratory pressure; Pmus, pressure from muscle contraction; R, resistance; Tm, transmural pressure; V, flow; V/Q, ventilation to perfusion ratio; Vt, tidal volume; WOB, work of breathing.

(heightened ventilatory response to minor CO_2 fluctuations), while plant gain is related to the modification in carbon dioxide tension (Pa_{CO_2}) resulting from a given change in ventilation. High loop gain predisposes to hyperventilation (overshoot) and subsequent lowering of Pa_{CO_2} below the apneic threshold, which is elevated during sleep. When CO_2 drops below the apneic threshold, a central apnea event (undershoot) occurs and lasts until the CO_2 increases above the threshold.[4] Therefore, Pa_{CO_2} levels oscillate above and below the apneic threshold, thereby causing the typical cyclical hyperventilation followed by central apnea pattern that defines CSR[5] (Fig. 148-3).

Treatment of these diverse Pa_{CO_2} disorders shares some common basic principles. In general, if the disorder is associated with underlying medical illnesses or medications, treatment of the underlying condition may improve the breathing disorder (e.g., downtitration of opioid doses in chronic opioid users or optimization of guideline-directed congestive heart failure therapy in CSR). When correction of the underlying problem is not achievable, the most frequently applied treatments are based on NIV therapy. In general, BPAP and volume-assured pressure support (VAPS) are modes usually recommended for patients with predominant alveolar hypoventilation in need of ventilatory support, while adaptive servo-ventilation (ASV) mode is indicated for patients with CSAS and preserved ventilation. However, phenotypic variance in breathing disorders and the individual response to NIV should be considered in the final decision of the optimal mode and settings (precision sleep medicine)[6,7] (Table 148-2).

Respiratory Failure Related to Hypoxemia Without Hypercapnia

Patients with hypoxemic (nonhypercapnic) respiratory failure are less likely to benefit from NIV. In these patients, hypoxemia is mainly the result of shunt, diffusion barrier, ventilation/perfusion (V/Q) mismatch, or a combination of these mechanisms (Fig. 148-2A). In these patients, systemic oxygen content depends mainly on hemoglobin and V/Q matching, and tends to plateau as minute ventilation (MV) or alveolar ventilation (V_A) are increased with bilevel PAP therapy. Therefore, choosing NIV in this population should take into consideration the etiology of hypoxemic respiratory failure and whether other forms of oxygen delivery (e.g., high-flow nasal cannula) may provide the oxygen support needed.[8]

■ Physiologic Effects of Pressure-targeted Noninvasive Ventilation

Below we discuss the cardiopulmonary effects of NIV, including potential adverse effects and contraindications to its use.

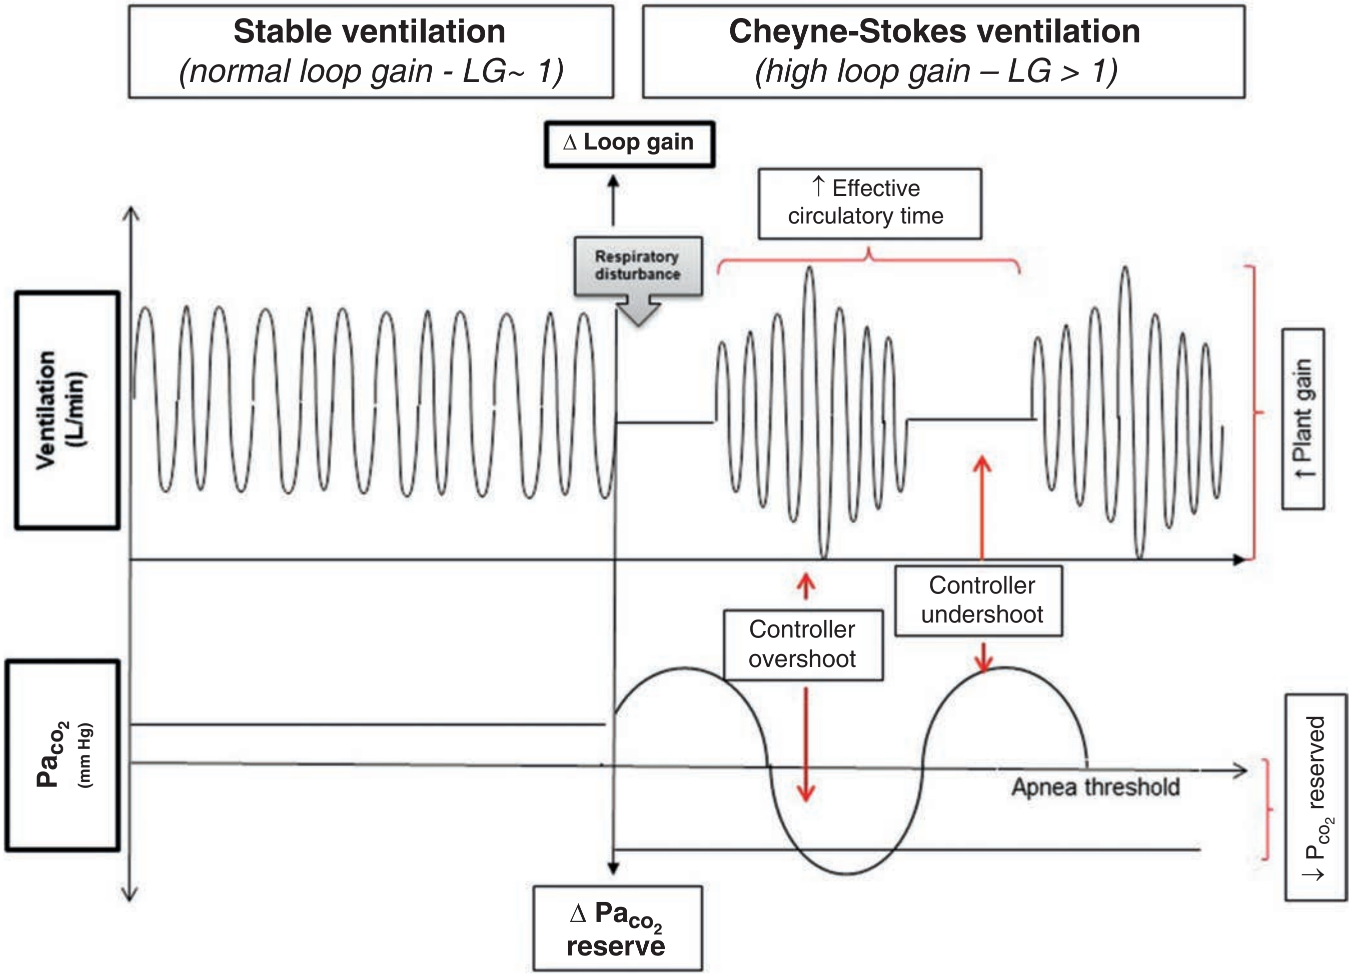

Figure 148-3 Hypocapnic respiratory failure—CSAS related to HF-CSR. CSAS, central sleep apnea syndrome; CSR, Cheyne-Stokes respiration; HF, heart failure; LG, loop gain; Pa_{CO_2}, tension of carbon dioxide.

Cardiopulmonary Effects of Positive Airway Pressure (PAP) Therapy

The pulmonary and cardiac systems are pressure chambers embedded into the thoracic cavity. By influencing each other as biologic pumps, they result in a direct mechanical interdependence. When PAP therapy is applied to an "active" breathing patient, the positive airway pressure will transmit along airways and alveoli into the pleural cavity resulting in increased (less negative) intrapleural pressure. This change will affect the transmural pressures of intrathoracic chambers such as the pericardial compartment, cardiac cavities, and blood vessels (e.g., vena cava).

Following a Starling resistor model in the upper airways, PAP therapy increases the intraluminal pharyngeal pressure resulting in a pneumatic splinting of those regions with propensity to collapse in OSA (e.g., retropalatal and retroglossal area).[1] Transmitted to distal airways and alveoli, positive airway pressure may facilitate a larger end-expiratory lung volume (prevent alveolar derecruitment), resulting in a higher oxygen reservoir and distal traction of the trachea with subsequent improvement of upper airway stability.[9,10]

During stable (unassisted) inhalation in a healthy individual, the resulting tidal volume will depend on the force generated by the respiratory muscle contraction (Pmus) to overcome the respiratory system load (respiratory system compliance, resistance, and intrinsic positive end-expiratory pressure [iPEEP]). This "work of breathing" is the summation of static work (energy required to maintain volume) and dynamic work (energy necessary to maintain flow and overcome resistance). When bilevel PAP therapy is implemented (assisted inhalation), the support and/or augmentation of the tidal volume and minute ventilation may unload the "work" of respiratory muscles and therefore decrease the work of breathing[11] (Fig. 148-2C).

The hemodynamic effects of positive intrathoracic pressure are complex and will depend on the interplay between several factors that regulate venous return and cardiac function. In general, the increase in intrathoracic pressure as a consequence of positive airway pressure therapy will affect the following four primary components of the circulatory system: (1) systemic venous return, (2) right ventricular output, (3) left ventricular filling, and (4) left ventricular cardiac output. The increase in intrathoracic pressure may result in an increase in vena cava resistance with subsequent reduction of venous return to the right atrium (decrease in right ventricular preload), an increase in pulmonary arterial resistance (increase in right ventricular afterload), and a reduction of venous return to the left atrium (decrease in left ventricular preload). Finally, the transmission of a more positive pleural pressure to the pericardial cavity will decrease the transmural pressure across the left ventricle, resulting in a reduction of left ventricular wall tension (decrease in left ventricular afterload)[12,13] (Fig. 148-2D). The consequences of these hemodynamic changes in clinical practice depend on the patient's cardiac function and volume status. Although homeostatic adaptation (e.g., decrease in vascular capacitance) to the application of PAP therapy will prevent hypotension in most euvolemic patients,

TABLE 148-2 Matching Noninvasive Ventilation (NIV) Modes to Pathophysiology: Indications

NIV Devices	NIV Action(s)	Pathophysiology Match—Indications
Bilevel positive airway pressure (BPAP) **Device that delivers a higher inspiratory pressure (IPAP) and a lower expiratory pressure (EPAP), potentially increasing tidal volumes, and hence, alveolar ventilation** - ***S: Spontaneous (no backup rate)*** - ***ST: Spontaneous-timed (backup rate)***	• Support/augment ventilation • Pneumatic splinting of upper airways • Backup rate is set when minimal minute ventilation is needed, or a mechanical breath is required during central apnea	**Hypercapnic respiratory failure with/without upper airways instability** • Alveolar hypoventilation *(BPAP-S or BPAP-ST mode to support minute ventilation)* **Central sleep apnea (CSA)** • Primary central sleep apnea *(BPAP-ST mode)* • Second-line treatment for CSA related to CHF *(CSR-CHF) (generally BPAP-ST mode)*
Volume-assured pressure support (VAPS) **Feedback control system with self-adjustable pressure support to target:** - ***Expiratory tidal volume (eVt)*** ***or*** - ***Target alveolar ventilation (VA)***	• Support/augment ventilation • Pneumatic splinting of upper airways • Backup rate is set when minimal minute ventilation is needed	**Hypercapnic respiratory failure with/without upper airways instability** • Alveolar hypoventilation *(neuromuscular or restrictive lung disease)* • OHS with failure to CPAP and/or BPAP-S or OHS without predominant OSA
Adaptive servo ventilation (ASV) **Feedback control system with self-adjustable pressures that target an average ventilation or inspiratory flow**	• Breathing pattern correction Note: avoid if hypoventilation syndrome is suspected or present	**Hypocapnic or normocapnic respiratory failure** • Systolic (EF ≥45%) or diastolic CSR-HF • Treatment of emergent central sleep apnea unresponsive to CPAP • CSAS due to long-acting opioids without carbon dioxide retention

elevated intrathoracic pressure may improve cardiac function in those with decompensated left heart failure.[14–16]

Potential Detrimental Effects of NIV

Acceptance of NIV is a complex process, and adaptation to the NIV machine can be challenging. Difficulties in becoming accustomed to the device may range from mild (air leak, claustrophobia, eye redness, rhinorrhea, mouth dryness, aerophagia, skin break at mask contact) to more serious side effects such as laryngeal spasm and patient–ventilator asynchronies, all of which can impair quality of life and affect compliance.

Asynchrony in the patient–ventilator interaction may have a profound impact on patient's compliance with therapy (e.g., intolerance, dyspnea) as well as detrimental effects on cardiorespiratory system mechanics. For example, an excess of inspiratory pressure may lead to overventilation (risk of volutrauma), overdistention (risk of barotrauma), and muscle overload (decreased neural inspiratory time with activation of expiratory muscles); excess expiratory pressure may compromise patient's hemodynamics (see "Pathophysiology: Decision Framework in Selecting NIV Modes," below). Furthermore, asynchronies in crucial points of pressure transitions from EPAP to IPAP (triggering) and back to EPAP (cycling) may also be detrimental (see "Advanced Settings and Dyssynchrony in NIV," below). Delayed (or missed) triggers may translate into pronounced dyspnea because of inappropriate isometric muscle load. In addition, early or premature mechanical breath termination (mismatch with neural inspiratory time) may result in excess muscle load and large tidal volumes as a result of double breaths (double triggering). In contrast, when breath termination is delayed, expiratory muscles may be recruited to terminate the inhalation.

Contraindications to NIV

There are few absolute contraindications for NIV use; important ones include (1) respiratory arrest or unstable cardiorespiratory status; (2) reduced consciousness and inability to protect the airway; (3) an uncooperative patient; (4) copious respiratory secretions; (5) severe nausea with vomiting; (6) facial trauma, burns, or craniofacial malformation; (7) certain head and neck–related surgeries or neurosurgeries; and (8) an air leak syndrome (e.g., pneumothorax with bronchopleural fistula).

■ Mechanical Anatomy of a Positive Airway Pressure Device (Hardware)

Positive airway pressure (PAP) devices (hardware) are portable flow generators capable of delivering positive air pressure to a patient via an interface (mask) or a tracheotomy tube. PAP devices are basically composed of a turbine ("dynamic blower system"—DC brushless motors), a respiratory circuit (a single or double hose), and a mask. Based on flow and pressure sensors (pneumotachograph) located in the device (device input), a microprocessor-based controller (governed by propriety algorithms) is constantly adjusting the turbine speed in order to reach a preset positive pressure (device output) stipulated by the provider. Because the pressure and flow sensor are within the device and not in the mask, the device must calculate the predicted pressure at the mask based on flow equations, adjusting the turbine speed in response to deviations in pressure that occur from leak or normal swings in air pressure as a result of the respiratory cycle.

PAP devices deliver positive pressure to the patient by hose(s) as part of respiratory circuits. There are two types of circuits: single-limb (one hose) or double-limb (two hoses). The single-limb circuit is a single tube for both inhalation and exhalation. To avoid carbon dioxide rebreathing, this system has a continuous exhaust port (intentional or controlled pressure leak) located either in the mask shell (vented mask) or in the swivel connector joining the hose to the mask (passive circuit). In contrast, the double-limb circuit is composed of separate inspiratory and expiratory limbs, and is generally used with an unvented mask (without an exhaust port) as carbon dioxide is directly expelled through the expiratory limb into the expiratory valve of the ventilator (active circuit). undergo automatic compensation for circuit compliance (drop pressure) and gas compressibility after setting the type of mask and the tube's length in the device's clinical menu[17] (Fig. 148-4).

The Basics: Modes (Software)

Based on their settings (mode), PAP devices may either deliver a single, continuous pressure (CPAP) during the respiratory cycle, or a higher inspiratory pressure (IPAP) and a lower expiratory pressure (EPAP) in the form of bilevel positive airway pressure (BPAP) mode, supporting and/or augmenting the patient's breath (tidal volumes), and hence, minute ventilation. Depending on the type of software, BPAP modes may interact differently with the breathing pattern, adjusting pressure accordingly using propriety algorithms (decision paths) designed to achieve a specific respiratory assistance (e.g., ventilation support in alveolar hypoventilation, or counterbalance compensatory respiratory support in Cheyne–Stokes respiration).

Bilevel PAP Modes (BPAP): Spontaneous (BPAP-S) and Spontaneous-timed (BPAP-ST)

The BPAP mode may cycle between two pressures, a higher IPAP and a lower EPAP, in response to the patient's respiratory effort (effort-triggered breath) or time to breath (time-triggered breath). While the IPAP augments inspiration, the EPAP (similar to CPAP) provides a pneumatic airway splint to maintain upper airway patency proximally and stable expiratory residual volume distally. The difference of the two pressures, called pressure support or delta pressure, contributes to improved ventilation through tidal breath support or augmentation. The larger the pressure support is, the larger the tidal volume generated with subsequent washout of Pa_{CO_2} (assuming a constant dead space). However, for a given patient, the tidal volume generated by BPAP is not fixed (nor guaranteed) and depends on the interplay of many important factors: preset settings in the device, patient's inspiratory time and effort, the dynamic characteristic of patient's respiratory system (resistance and compliance of the respiratory system), and the device's circuit (nonhermetic circuit, potential pressure leak) among others.

Based on the level of interaction with the patient's spontaneous respiratory effort, BPAP may be delivered in S (Spontaneous), ST (Spontaneous/Timed), and T (Timed) mode. In "spontaneous mode," the device senses when the patient is inhaling and exhaling and supplies the IPAP and EPAP accordingly. In "spontaneous/timed mode," the device will support and/or augment breaths initiated by the patient and supply additional breaths if patient's breath rate falls below a preset backup respiratory rate (RR). Although rarely used, the "T mode" delivers a fixed breath rate and duration and is a mode almost exclusively selected for those patients without (or with severely diminished) respiratory drive (Table 148-3, Fig. 148-5B).

Volume-Assured Pressure Support (VAPS) Mode

VAPS mode tracks a patient's spontaneous respiratory breath, proportionally adjusting IPAP and thus pressure support to augment breathing when needed to reach a respiratory target set by the provider. This respiratory target may be either expiratory tidal volume (eVt) or alveolar ventilation (V_A). In those cases where inadequate ventilation is due to (or exacerbated by) a decrease in respiratory rate (decreased respiratory drive), a backup respiratory rate will supply additional breaths to reach an adequate minute ventilation. An auto-EPAP function is also available in more recent device models to self-adjust to upper airway resistance (Table 148-3).

Manufacturer Differences in VAPS Modes by Respiratory Targets The VAPS algorithm patented in the "Average" Volume-Assured Pressure Support trademark (AVAPS, Philips) adjusts PS by varying the IPAP or PS level between a minimum (IPAP Min or PS Min) and a maximum (IPAP Max or PS Max) setting to match a target expiratory tidal volume (eVt) preset by the provider. The rate at which IPAP self-adjusts to achieve this targeted volume may be slow (by 1 cm H_2O/min) or fast (by up to 5 cm H_2O/min), and can be set in certain devices by the provider (VAPS rate). This proprietary algorithm analyzes the patient's spontaneous airflow to calculate the expiratory tidal volume (Vte), automatically adjusting trigger, cycle sensitivities, and pressure leak compensation (Auto-TRAK). In

some devices, Auto-TRAK is optional, allowing manual adjustment of trigger, rise time, and cycle (please refer to advanced settings in this chapter). In VAPS mode with auto-adjusting EPAP capability, the device also monitors the patient's upper airway resistance and automatically regulates the EPAP required to maintain upper airway patency. When the breath rate is set to Auto, the device will adjust the backup breath rate based on the patient's spontaneous respiratory rate, remaining two breaths below detected average spontaneous breathing until a higher backup rate is needed to maintain minute ventilation.

Different from Vte target by AVAPS, the "Intelligent" iVAPS (Resmed) targets a preset alveolar ventilation (V_A), adjusting for anatomic dead space calculated from the patient's height. By analyzing the patient's actual ventilation and respiratory rate, PS and the backup rate are continuously and proportionally self-adjusted to achieve and maintain the target V_A. In this mode, the backup rate is a factor in the V_A calculation, and is designed to be at two-thirds of the "baseline spontaneous patient's rate" (target patient rate) during spontaneous ventilation. However, during apneic events or decreased MV, the backup rate may escalate to "target patient rate." In VAPS mode with autoadjusting EPAP capability, the device will automatically regulate the EPAP required to maintain upper airway patency. The device may also contain a "Learn Target" feature, which allows the device to identify the patient's alveolar ventilation and spontaneous respiratory rate, and automatically uses these data as input in the device settings.

In general, VAPS mode can be activated in ST or Pressure Assist–Controlled (PAC) mode. Like in ST mode, inhalation in PAC mode is either initiated by the ventilator at a set rate (time-triggered breath) or the patient (spontaneous-triggered breath). However, different from ST mode, there is no spontaneous/flow cycling determined by the patient. The end of inspiration is controlled by the ventilator (time-cycled breath) by applying a fixed inspiratory time (Ti).

Adaptive Servo-ventilation (ASV) Mode

The ASV device supports breathing in a counterbalance proportional to the patient's breathing. When a patient's ventilation decreases, the ASV mode may provide higher respiratory support (i.e., minute ventilation or peak flow) by increasing inspiratory pressure support and/or respiratory rate. When ventilation returns to a more stable breathing pattern, this mode lowers support to a minimum. As the device detects a stronger breath, it automatically lowers the pressure support provided. This "on demand" breathing support allows a dampening effect on respiratory drive fluctuations, and is particularly useful in periodic breathing secondary to a highly unstable respiratory drive system (high loop gain) like CSR[18,19] (Table 148-3).

■ Advanced Settings and Dyssynchrony in NIV

If properly adjusted, NIV unloads ventilatory muscles and reduces the work of breathing by delivering pressure-supported breaths. For this to occur, the patient–ventilator interaction should achieve synchrony by aligning the device's settings with the patient's neural time (respiratory drive) and respiratory system mechanics (compliance and resistance). For this to happen, the NIV's flow and pressure delivery must synchronize with patient effort during all three mechanical phases of breath delivery: trigger (breath initiation), rise time and inspiratory time (flow/duration of flow), and cycling (breath termination).

Advanced Settings

A variety of advanced settings in use of NIV should be considered and are discussed below.

Trigger Sensitivity "Trigger sensitivity" sets the level of inspiratory flow change generated by the patient's initial inhalation effort, above which the device switches from EPAP (exhalation) to IPAP (inhalation). Changes in trigger sensitivity should be customized to a patient's pathophysiology and assessed at the bedside. In some devices, a proprietary algorithm continuously analyzes the flow waveform to determine the best trigger without the physician needing to adjust the setting manually (e.g., Auto-Trak, Respironics). However, the use of standard Auto-Trak assumes normal diaphragmatic strength. Therefore, it may be associated with asynchronies in COPD and neuromuscular disease patients (Fig. 148-5A).

Rise Time "Rise Time" sets the time (ms) it takes the device to transition from EPAP to IPAP (pressurization time). The shorter the rise time, the higher the flow generated. Therefore, a faster rise time may be helpful to improve comfort in those with "air hunger," while a slower rise can be helpful in those with bulbar disease or chest wall stiffness (Fig. 148-5A).

Inspiratory Time "Inspiratory time" (Ti) sets the time limit spent on IPAP (s). Together with PS, Ti is the main setting to determine Vt. The longer the time spent in inhalation, the larger the Vt (assuming constant pulmonary mechanics). Ti will also affect the expiratory time and therefore expiratory Vt in a respiratory cycle. Depending on the manufacturer and device's model, Ti may either apply to mandatory breaths (Respironics), or to spontaneous as well as to mandatory breaths (ResMed) in ST mode. In PC mode, all manufactures will deliver a fixed Ti in response to all breaths (Fig. 148-5A).

Cycle Sensitivity "Cycle sensitivity" sets the cycle out of IPAP into EPAP based on flow decay at the end of inhalation. Therefore, termination of inhalation support may be determined by either flow decay (percentage of decrement in flow as compared to the peak inspiratory flow noted at the initiation of inhalation) or by time (Ti). When the cycle is determined by the percentage of peak flow, the lower it is set, the later IPAP support will terminate. For example, in neuromuscular disease it may be set "low" to allow longer inhalation, while COPD patients may benefit from a "high" cycle sensitivity (Fig. 148-5A,C).

Manufacturer Differences in Advanced Settings

Manufacturer differences regarding cycling parameters may exist. For example, Resmed devices cycle out of IPAP in a "time window period." This cycle window is defined by a Ti min., which guarantees a minimal time in inhalation, so that a short, shallow breathing pattern does not develop in those with neuromuscular disorders. Ti max limits the maximal time in IPAP providing protection against hyperinflation in those with COPD or against late cycling in those with a large unintentional pressure leak from the mask. Between these two "time limit parameters" (or time window), the patient's spontaneous breath may cycle by flow decay.

In some NIV modes, the trigger and the cycle are automatically adjusted by the device (based on proprietary flow shape signal analysis) to reach maximal synchrony with the patient. In other NIV modes, manual adjustment of the trigger is possible by adjusting the "trigger sensitivity," which is the inspiratory flow set above which the device triggers in spontaneous mode. In the case of flow cycled breath, "cycle sensitivity" can also be manually set in the device by assigning a level of inhaled flow below which the device changes out of IPAP (Fig. 148-5C).

Patient–Ventilator Dyssynchrony

Patient–ventilator dyssynchrony occurs when the trigger, flow, and/or cycling of a mechanical breath is not in time agreement with the initiation and termination of a patient's neural inspiration, respectively, or if the magnitude of mechanical assist does not respond to the patient's respiratory demand. Dyssynchrony between the patient and the NIV mode may overload ventilatory muscles (respiratory load), compromise respiratory ventilation, disrupt sleep patterns, and cause patient discomfort with subsequent poor compliance. The most frequent asynchrony results from pressure leak from the mask, compromising triggering (delayed, missed, or auto-triggering), rise time, and Ti (flow), as well as cycling (premature or delayed). Once the mask pressure leak is resolved, if residual trigger asynchrony is identified, adjustment of the sensitivity setting should be a compromise between trigger difficulty and auto-triggering. Similarly, cycle asynchrony can occur if the inspiratory time is set too short (double triggering) or too long (active exhalation). This asynchrony can be addressed by appropriately setting the Ti and/or the cycle sensitivity[18,20,21] (Table 148-4).

Another respiratory support failure may be the result of increased resistance in the upper airway (e.g., OSA or glottic closure induced

TABLE 148-4 Troubleshooting Asynchronies

Asynchrony	Definition	Types	Action
Inspiratory triggering Industry default to *medium* sensitivity or Auto-Trak[a]	Mismatch between patient's inspiratory effort and ventilator triggering	Ineffective inspiratory effort	First: Minimize mask leak Second: Minimize UA resistance (OSA) Third: Set trigger sensitivity to *High* for very weak muscular effort (e.g., NMD or high PEEPi) or Auto-Trak sensitive
		Double triggering	Increase PS and/or decrease cycle sensitivity Extend Ti time in PC mode
		Autotriggering	Set trigger sensitivity to *Low* if device's inhalation starts before patient's inhalation
Cycling[a] Industry default to *medium* sensitivity or Auto-Trak[a]	Ventilator cycling does not coincide with end of patient's effort	Premature cycling (cycle before patient ends inhalation, long neuronal insp. time)	First: Minimize mask leak Second: Review Ti (or Ti max) Third: Set cycle sensitivity to *Low* (low % of peak flow) • Trial of Auto-Trak sensitive • Consider change to PC mode so that spontaneous triggered breaths will be fully supported
		Late cycling (cycle after patient ends inhalation, short neuronal insp. time)	First: Minimize mask leak Second: Review Ti (or Ti min) Third: Set cycle sensitivity to *High* (high % of peak flow)

[a] *Respironics program is based on automatic adjustments of trigger and cycle sensitivity called Auto-Trak sensitivity (this function also adjusts for mask leak).*

by hyperventilation). This may act as a barrier to effectively delivery of the required pressure support. Therefore, increasing the delivered inspiratory pressure or Ti during NIV will not necessarily result in increased effective ventilation reaching the lungs until an appropriate EPAP is set to maintain upper airway patency.

Differences Between Respiratory Assist Devices (RADs) and Ventilators

National and local coverage determination (NCD and LCD) reimbursement criteria for PAP devices, durable medical equipment (DME) coding, and current procedural terminology (CPT) coding are complex and governed by intricate national and local reimbursement policies. Historically, and based on criteria of cost and safety features offered by the device, coverage qualification criteria for NIV devices have traditionally differentiated between respiratory assist devices (RADs) and home mechanical ventilators (HMVs) (Table 148-5). RADs are, in general, portable, home-based, single-limb circuit bilevel PAP devices designed for noninvasive ventilation through a vented interface. In contrast, HMVs are, in general, devices that may deliver volume or pressure modes by single- or double-limb circuits designed for noninvasive ventilation through a mask or invasive ventilation through tracheotomy tube. Because

HMV devices are used in advanced respiratory failure ("life support"), they are usually set with safety alarms (e.g., for disconnection or critical volume and/or respiratory rate values) and batteries for autonomous function.

Although traditionally RADs and HMV varied in the features offered (modes, alarms, batteries), technologic developments have blurred the distinction between these two classes as RADS are becoming gradually more sophisticated, and HMV are becoming increasingly applied for chronic hypercapnic respiratory failure in need of NIV. Therefore, the practice of associating the type of NIV device to the degree of ventilator dependence, type of interface, or other feature may soon no longer be applicable based on technologic progress.

NONINVASIVE VENTILATION IN THE ACUTE CARE SETTING

Increasingly, NIV has come into widespread use in the acute care setting. A variety of applications are considered below.

Acute Cardiogenic Pulmonary Edema

Despite the use of supplemental oxygen and medications that decrease pulmonary edema and improve myocardial performance, many patients develop severe respiratory failure. The use of noninvasive positive airway pressure in patients with cardiogenic pulmonary edema was originally described nearly 85 years ago, and it was one of the first described indications for noninvasive mechanical ventilation in the acute setting.[22] When 39 consecutive patients with respiratory failure due to severe cardiogenic pulmonary edema were randomized to CPAP versus usual care, the use of NIV resulted in a significant decrease in the subsequent requirement for intubation and mechanical ventilation.[23] The physiologic benefits of continuous positive airway pressure among patients with acute cardiogenic pulmonary edema include preventing alveolar collapse at end-expiration, increasing hydrostatic pressure and forcing fluid out of the alveolar space and into the interstitial space, improving oxygenation, reducing preload, and decreasing left ventricular afterload. More recent data, including a meta-analysis of randomized, controlled trials in patients with acute cardiogenic pulmonary edema, demonstrated that NIV, usually in the form of CPAP, decreased the need for intubation, improved clinical and laboratory indices of respiratory failure, and improved mortality.[24–26] The effect was more prominent in trials that included patients in which myocardial ischemia or infarction caused the acute pulmonary edema. No differences were detected between CPAP and bilevel ventilation and any clinical outcomes for which they were directly compared.[27]

Acute Exacerbation of COPD

NIV is the preferred initial mode of ventilatory support for patients with acute exacerbations of COPD, if no contraindications exist. Usual indications include severe dyspnea, increased work of breathing, and respiratory acidosis. The use of NIV in patients with acute exacerbations of COPD is associated with a decreased respiratory rate, increased tidal volume, increased minute ventilation, decreased mortality, decreased intubation rates, and decreased length of stay.[27–29] The mechanisms by which bilevel NIV improves hypercapnic respiratory failure and acute exacerbations of COPD include improved alveolar ventilation through improved respiratory mechanics and improved gas exchange.[30,31]

Acute Exacerbation of Asthma

Unlike acute exacerbations of COPD, there is less evidence of benefit for the use of NIV among patients with acute asthma exacerbations.

Bilevel NIV is commonly used in patients with severe asthma exacerbation; however, data are limited to small randomized controlled trials[27] and two large retrospective studies[32,33] that have not documented a clear benefit on mortality or intubation rates. Larger randomized controlled trials are clearly needed in this domain. In this context, despite inconclusive data, short trials of NIV (usually with BPAP) could be considered in acute asthma exacerbation, especially among those not responding to medical therapy. Close observation and a low threshold to intubate if no improvement with NIV is recommended. In support of this approach is a randomized controlled trial that compared conventional asthma treatment with BPAP among 300 patients with severe asthmatic exacerbations admitted to the emergency department. The addition of BPAP to conventional treatment improves lung function, alleviated the exacerbation faster, and significantly reduced the need for hospitalization.[34]

■ Hypoxemic, Nonhypercapnic Respiratory Failure

In general, data are not as supportive of the use of NIV in this population compared to those with acute hypercapnic respiratory failure. The benefit from NIV likely varies in this nonhypercapnic phenotype due to the heterogeneity of this group. The most robust mortality benefit and reduction in intubation rates associated with NIV are driven by the subgroup of patients with pneumonia as the underlying cause of hypoxemia.[35] In contrast, most patients with ARDS require invasive mechanical ventilation, particularly for those with moderate to severe ARDS defined as Pa_{O_2}/Fi_{O_2} ratio of <200 mm Hg. Limited data indicate a high failure rate NIV in patients with Middle East respiratory syndrome (MERS)[36] and influenza.[37] Despite this, in several retrospective cohorts of COVID-19 patients, 11% to 56% of patients were treated with NIV.[38,39] On balance, in hypoxemic respiratory failure due to COVID-19, high-flow nasal cannula (HFNC) is favored over NIV based more on indirect data among non–COVID-19 patients with hypoxemic respiratory and the fact that it is a more practical mode of support, which allows patients to converse and eat, compared to NIV.[40]

■ NIV in Postoperative Care

Hypoxemia from atelectasis is a common postoperative pulmonary complication, particularly after thoracoabdominal procedures. Among patients with hypoxemia without significant secretions, CPAP may be of benefit. This was demonstrated in one multicenter, randomized, controlled trial that enrolled 209 consecutive patients with hypoxemia after major elective abdominal surgery.[41] In this study, patients were randomly assigned to receive either oxygen or oxygen plus CPAP. The group that received oxygen plus CPAP had a lower intubation rate, lower rate of pneumonia, lower infection rate, and lower rate of sepsis compared with those treated with oxygen alone. Although these findings have not been consistent across all studies,[42] it is likely that the benefits of CPAP in hypoxic patients with atelectasis and low secretion burden outweigh the risks as long as close monitoring is performed to assess the need for reintubation. Among patients unable to participate in incentive spirometry maneuvers, CPAP may also be of benefit as a lung expansion technique. In one trial, 500 patients scheduled for elective cardiac surgery were randomized to either 10 min of intermittent CPAP at 10 cm H_2O pressure every 4 h or continuous CPAP for at least 6 h. The continuous CPAP arm had significantly improved oxygenation, reduced pneumonia rates, reduced reintubation rates, and reduced admissions to the ICU.[43] More studies are needed to better determine the role of CPAP among postoperative patients, particularly in patients with obesity and underlying sleep-disordered breathing.

■ NIV in Extubation Management

In a meta-analysis of 16 trials involving 994 patients, the majority with chronic obstructive pulmonary disease (COPD), the use of extubation to NIV, compared with invasive positive pressure mechanical ventilation weaning, significantly decreased mortality. The mortality benefits were significantly greater in trials primarily enrolling participants with COPD (relative risk [RR] 0.36; 95% confidence interval [CI], 0.42–0.98) compared with mixed populations. Additional benefits to NIV included a reduction in weaning failure, reduction in ventilator-associated pneumonia, shorter length of stay in the ICU, a decrease in the total duration of ventilation, and a decrease in the duration of endotracheal mechanical ventilation. NIV also significantly reduced tracheostomy and reintubation rates.[44]

In one study, 97 patients requiring >48 h of mechanical ventilation and at risk of developing postextubation respiratory failure (i.e., patients who had hypercapnia, congestive heart failure, ineffective cough, excessive tracheobronchial secretions, more than one failure of a weaning trial, more than one comorbid condition, and upper airway obstruction) were randomized after a successful weaning trial to receive NIV for >8 h a day in the first 48 h or standard medical therapy.[45] Compared with standard medical therapy, the NIV group had a significantly lower rate of reintubation, and the need for reintubation was associated with a higher risk of mortality. Use of NIV was also associated with a reduction in intensive care unit mortality, which was mediated by the reduction in the need for reintubation.

CHRONIC DISEASE-DRIVEN USE OF NONINVASIVE MECHANICAL VENTILATION

Below we consider application of NIV in a variety of common clinical disorders that may be accompanied by hypercapnia.

■ Stable Hypercapnic Chronic Obstructive Pulmonary Disease

Hypercapnia is associated with a poor prognosis in COPD.[46] Studies dating back to the 1990s showed that nocturnal ventilation with either cuirass ventilation[47] or positive-pressure ventilation[48] reduced diurnal hypercapnia. However, early clinical studies of NIV showed little improvement or conflicting data in important clinical outcomes.[49] A 2013 Cochrane review (including 7 studies and 245 patients) found no improvement in gas exchange, 6-min walk distance, health-related quality of life (HRQOL), lung function, respiratory muscle strength, or sleep efficiency.[50] In subgroup analyses, significant differences in change in Pa_{CO_2} after 3 months were found in patients ventilated with IPAP of at least 18 cm H_2O, in patients who used NIV at least 5 h per night, and in patients with baseline Pa_{CO_2} at least 55 mm Hg.

Early studies of NIV in stable hypercapnic COPD mostly used BPAP therapy with low levels of pressure support (PS).[49] However, higher PS has been shown to reduce diaphragm activity to a greater extent than lower PS in COPD.[11] In a prospective randomized trial of "high intensity" NIV (targeted to reduce Pa_{CO_2} by ≥20% or <48.1 mm Hg) in patients with advanced COPD and Pa_{CO_2} at least 51.9 mm Hg, compared with no NIV, survival was significantly improved (1-year mortality 12% in the treated group and 33% in the control group). BPAP-ST was used with a mean IPAP of 21.6 cm H_2O, mean EPAP of 4.8 cm H_2O, and mean backup rate of 16.1 breaths per minute. Similarly, in the HOT-HMV trial, high-intensity NIV was associated with a reduction in a composite outcome of time to hospital readmission or death (driven primarily by hospital readmission) in patients with persistent hypoxemia and hypercapnia 2 to 4 weeks following an acute exacerbation.[51] In contrast, in the RESCUE trial, in which patients with advanced COPD were treated with high-intensity NIV (or no NIV) if Pa_{CO_2} remained >48 mm Hg 48 h after liberation from mechanical ventilation for COPD exacerbation, there was no difference in time to readmission or death.[52] A possible reason for this discrepancy may be that the patients in the RESCUE trial may not have been at baseline when

NIV was initiated. In the HOT-HMV trial, of 2021 potentially eligible patients, 419 (21%) were excluded because ABG no longer met eligibility criteria. These studies were conducted in Europe and may not be generalizable to a U.S. population.[53]

In a recent meta-analysis of NIV in stable hypercapnic COPD (21 randomized controlled trials and 12 observational studies; n = 51,085) NIV (delivered with a bilevel positive airway pressure device or mechanical ventilator) was associated with improvements in mortality and all-cause admission. Outcomes were not stratified by specific NIV mode or settings used.[54]

Guidelines for Use

A multicenter consensus conference (with representatives from the American Academy of Home Care Physicians, American Association for Respiratory Care [AARC], American College of Chest Physicians [ACCP], American College of Physicians, American Sleep Disorders Association, American Thoracic Society [ATS], and National Association for Medical Direction of Respiratory Care [NAMDRC]) held in 1999 recommended initiation of NIV in COPD in the presence of symptoms (e.g., fatigue, dyspnea, morning headache) and one of the following physiologic criteria: (1) Pa_{CO_2} $\geq$55 mm Hg, (2) Pa_{CO_2} of 50 to 54 mm Hg and nocturnal desaturation (Sp_{O_2} $\leq$88% for 5 continuous minutes on oxygen $\geq$2 L/min), or (3) Pa_{CO_2} of 50 to 54 mm Hg and hospitalization related to recurrent ($\geq$2 in a 12-month period) episodes of hypercapnic respiratory failure.[54] These ultimately informed the current Centers for Medicare and Medicaid (CMS) coverage decisions in place today. Note that CMS qualifying guidelines cover devices rather than modes. There are separate coverage determinations for (1) CPAP and less commonly used bilevel devices for OSA, (2) RADs for non-OSA ventilatory disorders, which are further divided into those without a backup rate (E0470) and those with a backup rate (E0471) and home mechanical ventilators delivered with a noninvasive interface (E0465) for chronic respiratory failure (Table 148-5).

Both the recent European Respiratory Society (ERS) guideline[56] and the recent ATS guideline[57] endorse NIV in chronic hypercapnic COPD (conditional recommendation, low-certainty evidence and conditional recommendation, moderate-certainty evidence, respectively). In light of emerging data, advances in NIV technology, and payer issues, a Technical Expert Panel with representatives from the American Academy of Sleep Medicine (AASM), AARC, ACCP and ATS has proposed new updated recommendations for initiation of NIV in COPD.[58,59]

Modes and Settings

Most studies of NIV in COPD have used BPAP-S or BPAP-ST. VAPS has been used in small studies with similar improvements in gas exchange, lung function, HRQOL, and sleep compared with BPAP-ST.[60,61] The ERS guideline suggests a fixed PS mode as the first-choice ventilator mode in COPD (conditional recommendation, very low-certainty evidence).[56] Mode is not addressed in the ATS guideline. Both the ERS guideline[56] and the ATS guideline[57] suggest a NIV titration strategy targeted to reduce or normalize Pa_{CO_2} (conditional recommendation, very low-certainty evidence and conditional recommendation, low-certainty evidence, respectively). An initial target tidal volume of 8 cc/kg ideal body weight has been suggested to be achieved by adjusting PS on BPAP-S, BPAP-ST, or VAPS, depending on the device available. A backup rate may better allow target Pa_{CO_2} to be achieved, but current CMS guidelines may preclude this, at least initially. EPAP is generally kept low unless upper airway obstruction. The authors suggest matching NIV settings to underlying pathophysiology (e.g., medium trigger sensitivity, fast rise time, short inspiratory time, and high cycle sensitivity)[7] (Table 148-6).

Initiation and Titration

Acute exacerbations of COPD (AECOPD) are associated with significant morbidity, mortality, and healthcare costs. The degree of hypercapnia and the timing of initiation of NIV in relation to AECOPD are likely important as evidenced by the contradictory results of the RESCUE trial (NIV initiated if Pa_{CO_2} >48 mm Hg 48 h after AECOPD)[52] and the HOT-HMV trial (NIV initiated if Pa_{CO_2} >53 mm Hg 2–4 weeks after AECOPD).[51] Those who remain significantly hypercapnic over time appear to be more likely to benefit from NIV. The ERS guideline suggests that “NIV be used in patients with COPD following a life-threatening episode of acute hypercapnic respiratory failure requiring acute NIV, if hypercapnia persists following the episode” (conditional recommendation, very low-certainty evidence).[56] The ATS guideline suggests “not initiating long-term NIV during an admission for acute-on-chronic respiratory failure, favoring reassessment for NIV at 2–4 weeks after resolution” (conditional recommendation, low-certainty evidence).[57]

In non-U.S. trials, long-term NIV is often initiated in the hospital or specialized home ventilation centers, sometimes with multiple admissions for acclimatization and serial adjustments.[51,62] This approach is not utilized in the United States. In-laboratory titration polysomnography (PSG) has been used clinically and can potentially optimize titration endpoints (e.g., target tidal volume, transcutaneous CO_2) and reduce patient–ventilator asynchrony. The AASM NIV Task Force recommends attended PSG for NIV titration in chronic alveolar hypoventilation syndromes,[63] but stable hypercapnic COPD was not specifically discussed. A recent randomized controlled trial showed noninferiority of a home-based approach (using trained nurses and telemedicine monitoring) compared

TABLE 148-6 Matching Noninvasive Ventilation Settings to Respiratory Pathophysiology

Advanced Settings	Chronic OHS	Chronic COPD	Chronic NMD
Trigger sensitivity	Default trigger sensitivity	Default trigger sensitivity	High trigger sensitivity (to support a weak respiratory muscular effort)
Rise time	Default or slow rise time	Fast rise time	Default or slow rise time
Inspiratory time (Ti)	Long Ti (to maximize Vt and gas exchange by ↑ I:E)	Short Ti (to increase expiratory time and minimize iPEEP by ↓ I:E)	Long Ti (to maximize Vt and gas exchange by ↑ I:E)
Cycle sensitivity	Default to low cycle sensitivity	Default to high cycle sensitivity (early cycle to provide a longer exhalation time (↓ I:E))	Default to low cycle sensitivity (late cycle) to provide a longer inhalation time (maximize Vt and gas exchange by ↑ I:E)

COPD, chronic obstructive pulmonary disease; I:E, inspiratory to expiratory ratio; iPEEP, intrinsic PEEP; NMD, neuromuscular disease; OHS, obesity hypoventilation syndrome; Ti, inspiratory time; Vt, tidal volume.

with a hospital approach.[64] There are minimal data on the utility of titration PSG compared with home initiation of NIV. In a small case series, titration PSG was beneficial in improving asynchrony and comfort in patients with dyspnea on therapy.[65] The ATS NIV in COPD guideline suggests "not using an in-laboratory overnight PSG to titrate NIV in patients with chronic stable hypercapnic COPD who are initiating NIV" (conditional recommendation, low-certainty evidence).[57]

■ Overlap Syndrome (Chronic Obstructive Pulmonary Disease and Obstructive Sleep Apnea)

Overlap syndrome (coexistent OSA and COPD)[66] is associated with a more severe nocturnal hypoxemia than either COPD or OSA alone.[67] Adverse cardiovascular outcomes, including pulmonary hypertension and right ventricular dysfunction, are more frequent.[68,69] Individuals with COPD with predominant chronic bronchitis phenotype may be at higher risk for coexistent OSA than those with predominant emphysema phenotype.[70] There are limited data on the utility of screening questionnaires for OSA in COPD,[71,72] and a high index of suspicion is needed. Despite imperfect screening tools, the ATS guideline does suggest screening for OSA in COPD (conditional recommendation, very low certainty),[57] in part because knowledge of the presence of OSA may lead to better titration (e.g., CPAP alone may be adequate; if bilevel modes used, EPAP will need to be adjusted for upper airway obstruction).

CPAP is the mainstay of therapy in OSA and is recommended as first-line therapy in moderate to severe disease.[73] In a long-term prospective study of patients with overlap syndrome,[74] those who were not treated with CPAP had higher mortality and were more likely to experience an AECOPD leading to hospitalization. Those with overlap syndrome treated with CPAP had similar mortality and AECOPD risk as those with COPD alone. In an observational, post-hoc analysis, greater time on CPAP was associated with reduced mortality in overlap syndrome.[75] BPAP has been used with success in individuals with overlap syndrome who fail CPAP due to residual respiratory disturbances, residual hypoxemia, or intolerance.[76] Auto-CPAP results in similar outcomes as CPAP in straightforward OSA,[77] but it has not been studied in patients with comorbid pulmonary disease.[78] There are no published randomized controlled trials comparing different positive airways pressure modes for overlap syndrome.

Guidelines for Use

The ATS NIV in chronic stable hypercapnic COPD guideline suggests clinical screening for OSA in COPD before initiating NIV (conditional recommendation, very low-certainty evidence).[57] There are multiple published guidelines on the evaluation and management of OSA[73,78,79] and on the titration of positive airway pressure therapy in OSA,[80] but none on the management of the overlap syndrome.

CMS has specific guidelines for initial coverage of CPAP for OSA including at least moderate OSA, as defined by apnea–hypopnea index (AHI) or respiratory event index (REI) ≥15 or mild OSA (defined by AHI or REI ≥5), plus qualifying symptoms (insomnia, excessive daytime sleepiness) and/or comorbidities (hypertension, ischemic heart disease, stroke, mood disorder). CMS covers BPAP-S for OSA in situations of documented CPAP failure (e.g., intolerance, residual sleep-disordered breathing).

Modes and Settings

Current practice supports CPAP as primary therapy for overlap syndrome. BPAP is reserved for those who fail CPAP (as defined by residual respiratory disturbances, residual hypoxemia, or intolerance). If BPAP is indicated, EPAP is adjusted to alleviate upper airway obstruction, and PS is adjusted to optimize ventilation.

Initiation and Titration

Sleep testing is indicated for the diagnosis of OSA.[81] The gold standard test is diagnostic PSG. If OSA is identified early in the night, a "split-night study" with the initiation of CPAP on the same night can be performed. Home sleep apnea testing is appropriate for the diagnosis of OSA in those with a high probability of moderate to severe OSA, but it is not recommended if significant pulmonary disease is present.[81] In individuals with underlying pulmonary disease, titration PSG is indicated to ensure resolution of obstructive events and correction of residual hypoxemia. CPAP alone may be adequate, but conversion to BPAP or addition of supplemental oxygen may be needed. Auto-CPAP has not been studied in overlap syndrome, and the authors suggest that this mode should be used cautiously if at all (e.g., with close monitoring of clinical status, PAP device data, and nocturnal oximetry), with a low threshold to perform titration PSG if suboptimal outcomes.

■ Obesity Hypoventilation Syndrome

Obesity hypoventilation syndrome (OHS) is defined by the presence of obesity (body mass index [BMI] ≥30 kg/m^2), sleep-disordered breathing (which may be obstructive or nonobstructive), Pa_{CO_2} ≥45 mm Hg, and the absence of other etiologies to explain hypoventilation.[82] In approximately 90% of individuals with OHS, the sleep-disordered breathing pattern is OSA, with 70% of these having severe OSA.[83] Although the pathophysiology of OHS is complex (Chapters 98–100), the repetitive, prolonged respiratory disturbances associated with cyclic hypoxemia and hypercapnia and relatively short inter-apneic intervals are thought to contribute to the development of diurnal hypercapnia.[84] The remaining 10% of individuals with OHS have nonobstructive sleep hypoventilation without (or with mild) OSA. OHS is associated with increased risk of pulmonary hypertension, cardiovascular and metabolic morbidity, hospitalization, intensive care admission, mortality, and health care utilization.[85–87]

The correction of diurnal hypoxemia and hypercapnia and improvement in symptoms with CPAP in OHS associated with severe OSA was first described in 1982.[88] Since then, multiple studies have been performed demonstrating the efficacy of positive airway pressure therapy in improving gas exchange, daytime sleepiness, sleep quality, quality of life, emergency department visits, and mortality.[89,90] In the largest randomized controlled study to date of OHS associated with severe OSA (n = 221), CPAP and NIV (delivered with VAPS) improved clinical symptoms and polysomnographic parameters better than lifestyle modifications at 2 months. Some HRQOL measurements, spirometry, and 6-min walk distance improved more with NIV than CPAP, but long-term implications of this finding are unknown.[83] In a randomized controlled trial of OHS without severe OSA (n = 98), NIV delivered with VAPS (compared with lifestyle intervention) was associated with improved gas exchange, quality of life, and daytime sleepiness but no change in hospital days/year over a median follow-up of 4.98 years.[91] In a systematic review of studies examining NIV versus CPAP as initial treatment in OHS (2994 potential articles found, 5 selected with sample sizes ranging from 36 to 225 subjects),[92] outcomes were similar between NIV and CPAP. The authors made a conditional recommendation that CPAP be offered as the first-line treatment in stable ambulatory patients with OHS and severe OSA.

In the minority of patients with OHS without significant OSA, NIV is typically used rather than CPAP. Additionally, NIV is also typically used in OHS in the inpatient setting when patients present with acute-on-chronic respiratory failure. Observational studies suggest higher mortality for patients discharged from the hospital without therapy (while awaiting further sleep evaluation) versus those discharged on NIV.[93]

Guidelines for Use

The ATS guideline on the evaluation and management of OHS endorses positive airway pressure therapy (CPAP or NIV) versus no therapy for stable ambulatory patients with OHS (conditional recommendation, very low level of certainty). Additionally, for those stable ambulatory patients with OHS with severe OSA, CPAP is recommended (rather than NIV) as first-line therapy (conditional recommendation, very low level of certainty). However, for hospitalized patients with respiratory failure and suspected OHS, NIV is recommended at discharge until outpatient workup and titration of positive airway pressure therapy can be performed, ideally within three months (conditional recommendation, very low level of certainty).[94] Other relevant published guidelines include those on the evaluation and management of OSA,[73,78,79] on titration of positive airway pressure therapy in OSA[80] and on titration of NIV in chronic alveolar hypoventilation syndromes including OHS.[63]

From a practical standpoint, CMS covers CPAP for OSA if (1) at least moderate OSA as defined by AHI or REI ≥15 or (2) mild OSA (defined by AHI or REI ≥5) plus qualifying symptoms (i.e., insomnia, excessive daytime sleepiness) and/or comorbidities (i.e., hypertension, ischemic heart disease, stroke, mood disorder). CMS covers BPAP-S for OSA in situations of documented CPAP failure (e.g., intolerance, residual sleep-disordered breathing). CMS coverage determination for respiratory assist devices for hypoventilation not associated with OSA is shown in Table 148-5, that is, starting with BPAP-S with a later option of transitioning to a device with a backup rate if failure of BPAP-S based on stringent criteria. The Technical Expert Panel has proposed new recommendations for initiation of NIV in OHS.[58,95]

Modes and Settings

Per ATS guideline on OHS,[94] CPAP is recommended (rather than NIV) as first-line therapy for stable ambulatory patients with OHS. BPAP-S may be required if intolerance at high pressures or persistent hypoxemia or hypercapnia. A backup rate is indicated in those with persistent hypoventilation (either due to inadequate respiratory rate or low tidal volume despite moderate to high pressure).

NIV with a backup rate (BPAP-ST and VAPS) is generally used in patients with OHS without significant OSA and in patients with respiratory failure. In a small, randomized crossover trial of VAPS versus BPAP-ST in OHS after failure of CPAP, VAPS and BPAP-ST resulted in similar improvements in oxygenation, sleep quality, and HRQOL. Transcutaneous CO_2 was lower with VAPS.[96] In another small study of VAPS versus BPAP-ST, VAPS was associated with a lower transcutaneous CO_2 but also objective and subjective impairment of sleep quality.[97] In a larger randomized controlled trial of VAPS versus fixed pressure support in OHS, there were no significant differences in gas exchange, somnolence, HRQOL, or sleep.[98] For empiric therapy in patients with suspected OHS with recent respiratory failure, VAPS with autoadjusting EPAP is theoretically advantageous while awaiting evaluation and titration. In a randomized controlled trial of a single night of VAPS with manual EPAP versus VAPS with autoadjusting EPAP in a mixed group of patients with chronic respiratory failure of diverse etiologies, VAPS with autoadjusting EPAP was noninferior.[99]

In OHS, EPAP is typically high (adjusted to eliminate upper airway obstruction), while PS is adjusted for an initial target tidal volume of 8 cc/kg ideal body weight and adjusted for ventilation. Prolonging the inspiratory time (Ti) may help optimize ventilation. The authors suggest matching NIV settings to underlying pathophysiology (e.g., low to medium trigger sensitivity, slow rise time, long inspiratory time, and low to medium cycle sensitivity)[17] as shown in Table 148-6.

Initiation and Titration

For stable ambulatory patients with obesity, Pa_{CO_2} ≥45 mm Hg, and the absence of other etiologies to explain hypoventilation, CPAP or NIV is initiated after the diagnosis of OSA[81] or non-OSA hypoventilation, respectively. Titration PSG (ideally with continuous CO_2 monitoring) is indicated to ensure resolution of obstructive events and correction of residual hypoxemia and hypercapnia.[63]

For patients who present with acute-on-chronic respiratory failure and suspected OHS, ATS OHS guidelines recommend discharge on NIV (settings based on clinical judgment) until outpatient evaluation and titration, ideally within 3 months. At that point, some patients may be able to be adequately titrated on CPAP while others may need to continue NIV.[100]

■ Neuromuscular Disease and Progressive Restrictive Thoracic Disorders

Neuromuscular and chest wall disorders constitute a diverse group of conditions that vary based on neuromuscular involvement, underlying cause, clinical presentation, and rate of progression, but are commonly associated with sleep-related alveolar hypoventilation and progression to hypercapnic respiratory failure.[101,102] Most studies have been done in amyotrophic lateral sclerosis (ALS) and Duchenne muscular dystrophy (DMD). NIV is associated with improvements in nocturnal and diurnal gas exchange, sleep quality, mortality, rate of lung function decline, quality of life, and symptoms.[103–110]

Guidelines for Use

There are multiple guidelines addressing NIV in patients with neuromuscular disease (NMD) and restrictive thoracic disorders (RTDs), some specific for ALS[105,108] or DMD,[111,112] while others cover a range of disorders.[55,109,113,114] In general, NIV is indicated for symptoms and signs of hypoventilation (e.g., orthopnea, disturbed sleep, reduced lung function, nocturnal hypoxemia, daytime hypercapnia).

Respiratory assist devices (with or without a backup rate) are covered by CMS in neuromuscular and chest wall disorders if criteria are met (Table 148-5). The Technical Expert Panel has proposed new recommendations for initiation of NIV.[58,115]

Modes and Settings

BPAP-ST is commonly used based on clinical experience, but VAPS is also acceptable.[17] Studies of VAPS versus fixed pressure support have been conflicting, but most studies were small and specific settings rather than modes may have explained results. In a case-crossover study of VAPS versus BPAP-ST in NMD/RTD, VAPS was associated with similar nocturnal oxygenation and sleep efficiency but increased nocturnal transcutaneous carbon dioxide tension.[116] This same group later studied VAPS with a modified VAPS algorithm versus BPAP-ST in a mixed group of NMD/RTD/COPD and found equivalent nocturnal oxygenation and ventilation at a lower median pressure support compared with BPAP-ST. Adherence was higher in the VAPS group.[117] In a retrospective chart review of VAPS versus fixed pressure support in ALS, VAPS was associated with a higher achieved tidal volume and a lower rapid shallow breathing index.[118]

With progression of neuromuscular weakness, there may be a need to transition to pressure control mode to better support ventilation or to use home mechanical ventilation to allow for mouthpiece ventilation during the day. Bulbar weakness may limit NIV tolerance. The initial target tidal volume is 6 to 8 cc/kg ideal body weight,[63] adjusted over time for ventilation. EPAP is generally kept low (unless coexistent upper airway obstruction), and IPAP is generally moderate (in the absence of parenchymal lung disease or significant load, e.g., obesity). The authors suggest matching NIV settings to underlying pathophysiology (e.g., high trigger sensitivity, slow rise time, long inspiratory time, and low cycle sensitivity)[17] as shown in Table 148-6.

Initiation and Titration

Given logistical difficulties, NIV is often initiated empirically in patients with neuromuscular disease. The AASM 2010 best clinical practices guideline for NIV in chronic alveolar hypoventilation recommends titration PSG, if possible, to optimize NIV settings and minimize patient–ventilator asynchrony.[63] Data are lacking, but a prospective observational study showed improvements in ventilation, sleep quality, quality of life, and adherence with an intensive NIV titration approach.[110]

■ Central Sleep Apnea

Central sleep apnea (CSA) is not one diagnosis and whether to treat and how to treat depends on the underlying etiology (Chapter 98). CSA may be primary or may be secondary to other disorders. CSA may also be divided into CSA associated with hypoventilation and CSA associated with hyperventilation.

CSA may be seen in severe hypoventilation disorders, including central hypoventilation disorders (e.g., congenital hypoventilation syndromes) or as a component of hypoventilation in other disorders (e.g., "pseudocentral" apneas in neuromuscular disease).[119] By definition, these disorders are associated with wake or sleep hypercapnia, and NIV is generally indicated. More commonly, CSA is associated with hyperventilation (i.e., hypocapnia) and high loop gain. Examples include primary (idiopathic) CSA, high altitude periodic breathing, and CSA associated with Cheyne–Stokes respiration in heart failure or stroke. CSA associated with medications (e.g., opiates) may have features of both hypoventilation and hyperventilation.

CSA may be associated with sleep disruption and daytime consequences. Repetitive desaturations may occur, which in turn may have physiologic consequences. However, whether CSA, per se, is responsible for excess mortality in Cheyne–Stokes respiration in heart failure, high-altitude periodic breathing, primary CSA, or opiate-induced CSA is not clear.[120] Often the treatment of CSA involves treating the underlying disorder (e.g., managing heart failure or reducing opiates). Therapies other than positive airway pressure therapy (e.g., oxygen, acetazolamide) may have benefits in some cases, and CPAP and other modes of positive airway pressure therapy may have a role in stabilizing breathing.[121] Most of the data on positive airway pressure for treatment of CSA comes from studies of Cheyne–Stokes respiration in heart failure.

CPAP has been shown to reduce central apneas in heart failure in several studies, the largest of which is the Canadian Continuous Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure (CANPAP) trial ($n = 258$). In comparison with no CPAP, CPAP-treated patients had improvements in respiratory disturbances, oxygenation, ejection fraction, and 6-min walk distance at 3 months.[122] However, followed over 2 years, there was no difference in transplant-free survival. In a posthoc analysis, those who were effectively treated with CPAP had better transplant-free survival.[123]

ASV improves central apnea in heart failure.[121] However, in the largest trial to date of CSA in symptomatic heart failure with reduced ejection fraction ($\leq 45\%$) (SERVE-HF, $n = 1325$), ASV was associated with increased mortality.[124] Opioid-related CSA may respond to ASV.[125,126]

Only a few small studies have evaluated BPAP-ST for treatment of CSA in heart failure.[121]

Guidelines for Use

The 2012 AASM practice parameters[121] on the treatment of CSA in adults recommended CPAP therapy for the initial treatment of CSA related to congestive heart failure. ASV was also indicated at that time for the treatment of CSA, but this recommendation was modified in the 2016 update following the publication of the SERVE-HF trial.[127] The update recommended against the use of ASV in patients with moderate-severe CSA and left ventricular ejection fraction $\leq 45\%$ and recommended ASV as an option in patients with CSA with ejection fraction $>45\%$ or mild CSA. Finally, the 2012 guideline stated that BPAP-ST might be considered for the treatment of CSA related to congestive heart failure if there is no response to adequate trials of CPAP, ASV, and oxygen therapies.

Modes and Settings

Studies directly comparing different modes of positive airway pressure therapy in CSA are lacking.[128] CPAP targeted to reduce respiratory disturbances is currently recommended first-line, with ASV as an option for those heart failure patients with reduced ejection fraction above 45% or those with preserved ejection fraction. BPAP-S often worsens CSA due to hyperventilation. However, BPAP-ST can theoretically improve CSA. In one small study comparing CPAP and BPAP-ST, outcomes at 2 weeks were similar.[129]

Initiation and Titration

Treatment of CSA with positive airway pressure therapy may be considered after the diagnosis is established by sleep testing. Not all patients require positive airway pressure therapy. If a decision is made to treat with positive airway pressure therapy, a titration study is indicated. A not-uncommon form of CSA is CPAP-emergent central apneas (i.e., central apneas that "emerge" in patients with OSA during CPAP titration). These may resolve over time on CPAP but may be less likely to resolve in the setting of cardiomyopathy or in patients who are older, have higher residual device-detected respiratory disturbances, or who have leaks,[130] and other PAP modes may need to be considered.

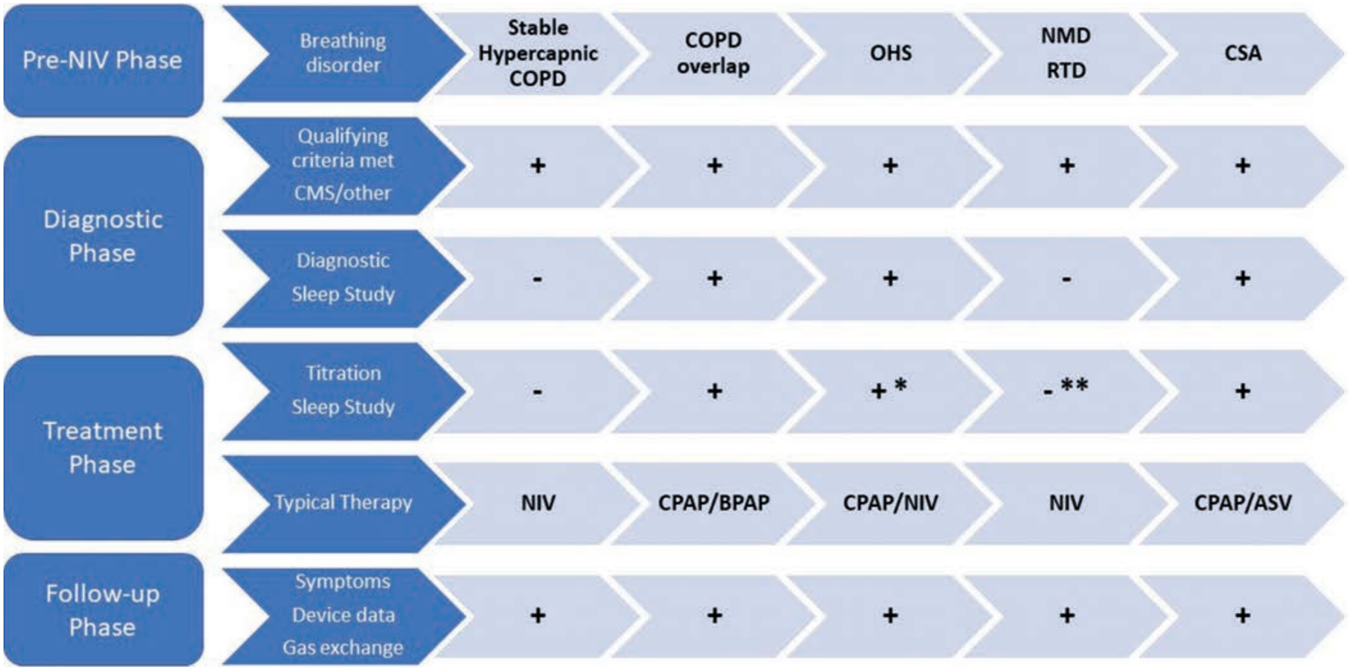
LONG-TERM MANAGEMENT OF NONINVASIVE MECHANICAL VENTILATION

Management of patients treated with NIV does not stop with the initiation of therapy. Instead, follow-up is part of the care continuum for such patients (Fig. 148-6). As noted above, therapy may be initiated empirically. Even if therapeutic PSG is used to guide initial therapy, not all goals of titration may be met on a single study night. For example, achieving a 20% fall in Pa_{CO_2} in one night of titration in severe stable hypercapnic COPD is often not feasible.[57] Respiratory status may improve or decline from the time NIV is initiated. AASM best clinical practice guideline for NIV in chronic alveolar hypoventilation syndromes recommends close follow-up after initiation of NIV to establish effective utilization patterns (ideally using objective data), remediate potential problems, and assess measures of ventilation and oxygenation to determine if adjustment to NIV is indicated.[63] CMS guidelines currently require follow-up including objective assessments of adherence for ongoing coverage of positive airway pressure devices.

■ Noninvasive Ventilation Device Downloads

Current NIV devices monitor usage, leak, and efficacy.[131] Usage data include the number of hours used per night as well as the clock times on and off the mask. Low use or variable use with frequent interruptions per night may indicate problems with asynchrony or intolerance and warrant further investigation. On a practical note, for OSA, CMS requires usage at least 4 h per night on at least 70% of nights to qualify for ongoing CPAP therapy coverage. Documentation of device usage is also required for RADs.

Leak includes intentional leak as well as unintentional leak. High unintentional leak is an indication of a problem with the interface or the circuit and needs to be addressed. Leak affects the performance of the device, including pressure delivered, cycle and trigger



Pre-NIV Phase	Breathing disorder	Stable Hypercapnic COPD	COPD overlap	OHS	NMD RTD	CSA
Diagnostic Phase	Qualifying criteria met CMS/other	+	+	+	+	+

Follow-up Phase	Symptoms Device data Gas exchange	+	+	+	+	+

Figure 148-6 Phases of care continuum in sleep-related breathing disorders treated with positive airway pressure therapy. ASV, adaptive servo ventilation; BPAP, bilevel positive airway pressure; COPD, chronic obstructive pulmonary disease; CPAP, continuous positive airway pressure; CSA, central sleep apnea; NIV, noninvasive ventilation; NMD, neuromuscular disease; OHS, obesity hypoventilation syndrome; RTD, restrictive thoracic disorder; +, indicated; -, not necessary. *Titration study is indicated in stable ambulatory OHS, but may be deferred for several months in favor of empiric therapy in patients with respiratory failure **Titration study is not required in neuromuscular disease, but is recommended if possible.

thresholds, and respiratory event determination.[132] Not only is leak associated with poor tolerance of therapy, but high leaks may also make therapy less effective. Device algorithms do not function optimally in the presence of high leak.

Efficacy of therapy may be determined by review of the synthesis report, which includes device-detected apnea–hypopnea index (AHI), exhaled tidal volume, respiratory rate, minute ventilation, and respiratory cycles triggered by the patient. The AHI is determined by the device algorithm, which is similar to but not the same as the AHI detected on PSG. AHI detected by NIV correlates well with AHI detected by PSG in OHS, assuming low leak and low asynchrony index.[133] Exhaled tidal volume (on noninvasive bilevel devices) is estimated rather than measured, and accuracy varies between devices.[134] Device-detected respiratory rate and rapid shallow breathing index (respiratory rate/tidal volume ratio) may be useful in assessing respiratory muscle rest versus fatigue.[118] Depending on the device and manufacturer, detailed data (e.g., tidal volume, minute ventilation, respiratory rate, flow, pressure, AHI) may be available to review cycle by cycle.[131] Some devices accommodate an external module that allows simultaneous recording of oximetry and heart rate.

Respiratory Monitoring

For disorders associated with alveolar hypoventilation (COPD, OHS, NMD, RTD), periodic measurement of Pa_{CO_2} is indicated to ensure that goals of treatment are being met. However, arterial blood gas testing during daytime, while important to assess diurnal ventilation, does not ensure that nocturnal ventilation is adequate.

Nocturnal CO_2 monitoring is preferred to diurnal testing for the measurement of sleep-related hypoventilation.[135] Transcutaneous CO_2 monitoring shows good agreement with Pa_{CO_2}[136,137] and is preferred to end-tidal CO_2 monitoring in patients using NIV.[131] Home-based transcutaneous CO_2 monitoring is feasible[138] but is not yet widely available in the United States.

Continuous nocturnal pulse oximetry is readily available and recommended to assess oxygenation on NIV.[63] However, there are some limitations.[131] Oximeter features (e.g., sampling frequency, signal averaging time) and motion artifacts affect results. Variations in pulse oximetry on NIV may be due to residual obstructive or central respiratory disturbances, decreases in ventilation, or pressure leaks. Prolonged desaturations may reflect periods of ventilation–perfusion mismatch, hypoventilation, leaks, or inadequate pressure support. In the presence of supplemental oxygen use, pulse oximetry is not sensitive for the detection of partial obstruction of upper airways (e.g., hypopneas) or hypoventilation. Guidelines for optimal oxygen saturation on NIV are not available; a suggested goal is a mean nocturnal oxygen saturation $\geq$90% with $<$10% time with oxygen saturation $<$90% after correction of leaks.[131]

Indications for Sleep Testing

As noted above and shown in Fig. 148-6, diagnostic sleep testing is indicated prior to initiation of CPAP or NIV in disorders in which obstructive or central apnea is a major component (i.e., COPD-overlap, OHS, or CSA). Diagnostic sleep testing is not necessary in stable hypercapnic COPD, NMD, or RTD in the absence of symptoms or signs of OSA.

Titration PSG could be helpful in stable hypercapnic COPD but is not recommended based on recent ATS guidelines.[57] Titration PSG is indicated in COPD-overlap syndrome. Titration PSG is also indicated in OHS, with the exception that it can be delayed in favor of empiric NIV for those being discharged from acute care for acute-on-chronic respiratory failure.[94] Titration PSG is not necessary and is often not practical in NMD, but it is recommended if possible.[63] Titration PSG is indicated in CSA.

Once established on CPAP or NIV therapy, follow-up includes clinical and objective reassessment, as noted above. One algorithm for monitoring NIV proposes targets, including (1) reduction in diurnal Pa_{CO_2} or nocturnal transcutaneous CO_2, (2) mean nocturnal oxygen saturation >90% for more than 90% of recording time, and (3) adequate use of at least 4 h per night without periods of fragmented use. If targets are not being met, the first step is an assessment of pressure leaks (to be corrected with mask assessment/refitting) followed by targeted adjustments in device settings if needed (e.g., increasing EPAP if upper airway instability, increase in pressure support if hypoventilation). If these fail to alleviate problems, repeat titration PSG may be indicated to optimize therapy.[139]

CHAPTER 149

Extracorporeal Membrane Oxygenation (ECMO) in Acute Respiratory Failure

Asad Ali Usman
Jacob Gutsche

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO), used synonymously with the term *extracorporeal life support*, can be traced back to the extracorporeal circuit invented by Gibbon first used successfully for cardiopulmonary bypass in 1953.[1] More recent advances in cannula, pump, and oxygenator design have improved the durability and availability of ECMO devices, making them available for widespread use.

Generally, an ECMO circuit consists of an inflow cannula that drains blood from the patient into the circuit, a pump to maintain flow, a membrane oxygenator, and an outflow cannula to return blood to the patient (Fig. 149-1). Two types of circuits are in use: veno-arterial (VA) ECMO for support of the heart and lungs, and veno-venous (VV) ECMO for support of the lungs. ECMO proceduralists have introduced multiple variations of these basic circuits to tailor the circuit design to specific types of cardiopulmonary failure. The circuits may be used as a bridge to recovery in patients with cardiopulmonary failure, and they have been used for weeks to months as a bridge to other options, such as a durable ventricular assist device or organ transplant.

In this chapter, we review the history and evolution of ECMO, the basics of circuit design and management, indications and criteria for use of ECMO, and the most common problems encountered. Although we focus on use of ECMO for pulmonary support, it is important for the clinician to understand use of ECMO for *cardiopulmonary* support, since there is overlap in use.

EVOLUTION OF ECMO

The use of ECMO as therapy for acute respiratory distress syndrome (ARDS) and acute respiratory failure (ARF) has evolved over the past 50 years in the context of a complex interplay among improvements in intensive care unit (ICU) therapies (e.g., paralysis, prone positioning, and low stretch ventilation), ICU systems (e.g., delivery of care; automation; electronic medical records; systems improvements, including better patient transport and care team dynamics), and ECMO technology.

ECMO developed as a natural progression from the traditional cardiopulmonary bypass circuit initially used in 1953 to perform the first successful open-heart surgery on an 18-year-old woman with an atrial septal defect.[1] The original circuit was only able to support patients for a very limited time due to the high rate of trauma

of blood components caused by their direct exposure to machine surfaces and oxygen.[2,3] Early challenges encountered with ECMO included poor gas permeability of the oxygenator (see below), weak structural integrity of the circuit, and poor biocompatibility of materials, resulting in sluggish blood flow. As material sciences progressed, new biopolymers were used as conduits for oxygen and carbon dioxide exchange, including Teflon, silicone dimethylpolysiloxane, and nylon. Another breakthrough occurred with development of a new capillary model for the blood–gas interface membrane that utilized a thin-lattice matrix (channels separated by 100–500 μm).[4,5]

The biophysics of extracorporeal membrane gas exchange is similar to that of gas exchange in mitochondria. In mitochondria, oxygen diffuses down a differential gradient from hemoglobin into the mitochondria, and CO_2 diffuses from mitochondria into the blood.[6,7] In ECMO oxygenators, the membrane consists of a lattice structure with a high surface area, and gas is introduced into a capillary-like tubing system—essentially opposite to what is found in the human circulation, where *blood* flows through the capillaries.

In modern-day ECMO oxygenators, blood circulates freely between the hollow fiber tubing carrying fresh gas, and oxygen diffuses through the membrane into the blood, which is propelled by a centrifugal pump. Hence, the gas tubing is akin to an alveolus. A typical red blood cell diameter is 8 μm, while the membrane pore size is <1 μm. The distance from the gas tubule to the blood (the *diffusion path*) is approximately 75 linear μm; however, the path from the fresh gas flow tube to the blood boundary layer is nonlinear due to the lattice matrix and is approximately 100 μm in length.[5]

In 1972 the first successful use of ECMO in a patient with trauma-induced ARDS was reported.[8] The patient was placed on VA ECMO for 75 h for refractory hypoxemia.[8] Importantly, at the time, standard ventilator settings included extremely high tidal volumes (>10 mL/kg) and lower levels of positive end-expiratory pressure (PEEP) than are commonly used today. This and subsequent reports in the literature prompted physicians to consider ECMO as possible salvage therapy for severe ARDS.[9–11]

The first multicenter clinical trial studying VA ECMO in patients with ARDS was completed in 1979.[12] Unfortunately, the study reported dismal results and was terminated early. Only 4 of 42 patients survived the interventional ECMO arm (although only 4 of the 48 patients survived the non-ECMO arm). Although a diagnosis of severe ARDS, irrespective of the treatment, portended a death sentence in the 1970s, the results from this trial demonstrated that VA ECMO did not improve outcomes. Many investigators now acknowledge that the trial was poorly constructed and, perhaps, executed too early in the technologic arc of ECMO and in the absence of institutional best practices. Furthermore, several other key aspects of ARDS care were yet to be established, such as prone positioning, low-stretch ventilation, and routine use of paralytic agents. Nonetheless, study results led to a strong aversion to the use of ECMO in ARDS, setting back development and application of ECMO by several years.

Subsequent studies on ECMO were based on the hypothesis that, perhaps, *CO_2 removal alone*, without targeting optimal oxygenation, might result in improved outcomes in ARDS. Gattinoni et al. suggested a paradigm based on the concept of "lung rest," in which ventilator settings (e.g., inflation volume) are minimized to avoid ventilator-induced lung injury.[13] In this model, the ECMO circuit is set to run at low rates of blood flow (0.5–2 LPM), targeting CO_2 removal only, and the ventilator is adjusted to low-frequency, positive-pressure ventilation to provide oxygenation.

A randomized controlled trial, published in 1994, compared use of ECMO for CO_2 removal versus standard care for patients with ARDS. Unfortunately, the trial was terminated due to lower survival in the ECMO group.[14] In addition, a second study was conducted, but was poorly designed to assess Extracorporeal carbon dioxide removal ($ECCO_2R$) because it encompassed two different experimental modalities. The protocol included use of pressure-controlled, inverse ratio ventilation in addition to low-frequency, positive-pressure ventilation; therefore, $ECCO_2R$ was implemented using two different ventilator settings. Ultimately, the investigators found improved oxygenation with $ECCO_2R$, demonstrated by higher ratio of Pa_{O_2} to F_{IO_2} (P/F ratio), but no difference in mortality (42% in the conventional arm with mechanical ventilation alone vs. 33% in the pressure-controlled, inverse ratio ventilation plus low-frequency, positive-pressure ventilation–$ECCO_2R$ group).[13] Notably, when compared with the absolute survival rate of ARDS in 1979, the 1994 study revealed a marked improvement with conventional management, that is, without using ECMO (survival increase from 8.3% to 58%).

In contrast, in neonatal and pediatric populations, ECMO found a home, prompting additional research and further advancements.[15] One example includes development of hollow-bore fiber tubing that is non-microporous and incorporates use of poly-4-methyl-1-pentene–based materials.[16] Poly-4-methyl-1-pentene oxygenators outperform older silicone dimethylpolysiloxane oxygenators due to lower platelet consumption, better gas exchange, and improved pressure drop requirements.[17,18]

Additional technologic developments in the past 10 years have produced devices designed to facilitate percutaneous cannula insertion.[19] Examples include a multitude of wires, catheters, and ultrasound techniques that have made percutaneous access the preferred choice for ECMO cannulation, resulting in reduced infection rates and bleeding risk.[19–21] Heparin-bonded cannulas and wire reinforcement allow peripherally inserted percutaneous catheters to remain in place without malfunction for weeks to months.[22–24] Wire reinforcement prevents kinking and collapse when negative pressure is applied to the catheter.[25] Additionally, bio-coated catheters and tubing which have a hydrophilic outer layer and contain negatively charged groups to repel negatively charged proteins and platelets have been developed, thereby creating a layer between blood and the artificial surface.[26] Development of dual-lumen, single-access cannulas has further decreased the vascular access burden faced by patients with ARF requiring extracorporeal support. Complications and iatrogenic effects of ECMO have been diminished with use of coated tubing; improved monitoring for anticoagulation; improved medication regimens, ICU management, and nursing care; and increased experience in tertiary centers.

Finally, during the last 25 years, as the definition of ARDS has evolved, considerations regarding the clinical application of ECMO have as well. In 1994 the American Thoracic Society and the European Society of Intensive Care Medicine, with the support of the NHLBI, published the American-European Consensus Conference (AECC) definition for ARDS.[14] AECC criteria were used in the pivotal studies on low-stretch ventilation. The AECC definition standardized the P/F ratio, application of chest radiography, and use of mild, moderate, and severe categories of disease, leading to the Berlin definition of ARDS.[27] By better defining the problem, further clinical trials could be conducted and compared. Against this backdrop, new studies of ECMO in ARDS were initiated. Several important examples are considered below.

■ CESAR Trial

The first major positive ECMO clinical trial was conducted in 2009. Called the Conventional Ventilation or ECMO for Severe Adult Respiratory Failure (CESAR) trial,[28] the trial was a prospective, randomized controlled study of 180 subjects. Patients were randomized to either conventional management or transfer to a quaternary center with ECMO capability for consideration for VV ECMO. Patients on mechanical ventilation >7 days and with inspiratory pressures >30 cm H_2O or F_{IO_2} >80% were excluded. Only 76% of patients randomized to transfer for ECMO consideration were actually placed on ECMO. The other 24% were further medically optimized.

The primary outcome was death or severe disability at 6 months. The study outcome favored ECMO intervention, with 37% mortality at 6 months in the ECMO group versus 53% in the conventional management group. The CESAR trial helped support development of ECMO centers of clinical excellence.

ECMO During the H1N1 Pandemic

In 2009 the H1N1 influenza pandemic led to several seminal publications which described the experience with ECMO in viral pneumonia with ARDS, thereby spurring further interest in expanding ECMO access.[29–33] The largest H1N1 series reported 68 subjects treated with ECMO in 15 ICUs. The average P/F ratio was 56, the initial pH 7.2, and the average PEEP 18 cm H_2O. Patients placed on VV ECMO had a survival rate of 78%.[29] The international impact of H1N1 and the success of VV ECMO led to an inflection point in VV ECMO use.[34]

EOLIA Trial

The Extracorporeal Membrane Oxygenation for Severe Acute Respiratory Distress Syndrome (EOLIA) trial, published in 2018, was a prospective, multicenter trial which randomized patients with ARDS to VV ECMO versus conventional treatment.[35] The target sample size of 331 patients was powered to detect an absolute risk reduction of 20% based on an expected 60-day mortality of 60% in the conventional arm and 40% mortality in the ECMO arm. Conducted at 64 centers, trial inclusion criteria were mechanical ventilation <7 days, P/F ratio <50 for >3 h or <80 for >6 h, and an arterial blood pH ≤ 7.2. Exclusion criteria included pregnancy, morbid obesity, underlying irreversible chronic respiratory insufficiency, cardiac failure requiring VA ECMO, cancer with short life expectancy, prior cardiac arrest, do-not-resuscitate status or withdrawal of care orders, or difficult vascular access. No statistically significant difference in mortality at 60 days was noted between the ECMO group (44/124, 35%) versus the control group (57/125, 46%) on interim analysis. The study found that the ECMO group did have lower risk of treatment failure, lower risk of renal replacement, and decreased requirement for prone positioning. Investigators also found that 35 of 125 patients crossed over into the ECMO group, which occurred at a median of 4 days. Mortality was higher in the crossover group. ECMO was associated with severe thrombocytopenia, more bleeding events, and fewer ischemic strokes. Based on predefined stopping rules, the data safety and monitoring board stopped the EOLIA trial early due to futility, noting no difference in survival between the ECMO and conventional therapy groups.

Notable is that there were several serious statistical limitations to the EOLIA trial, including the implausible power calculation performed prior to the study, which eventually resulted in early termination of the trial. The trial assumed a mortality of 60% in the conventional group, but the study's own conventional treatment group had a mortality of only 46%. As mentioned previously for the CESAR trial, the mortality from ARDS in the conventional management (mechanical ventilation) group was 53%. Furthermore, the absolute risk reduction to reject the null hypothesis in the EOLIA trial was set at 20% less in the ECMO group compared to the conventional management group.

As for the CESAR trial, and as in clinical practice, when faced with extreme ARDS and a high risk of mortality, withholding ECMO in the EOLIA trial was considered unethical; therefore, the crossover rate was high. This approach would be especially true if the clinician has a positive prior opinion on the benefits of ECMO and the patient is at an ECMO center. Due to the high degree of crossover, the final study results are biased against ECMO treatment because the crossover occurred after a period of conventional management, exposing the ECMO-delayed group to a longer duration of MV, lack of lung-rest, and delayed treatment. Additionally, this subgroup of "delayed ECMO" might represent an ARDS phenotype that should have received *early* ECMO and, therefore, carried a higher mortality.

Secondary limiting factors for the generalizability of the EOLIA trial include the duration of the trial, which lasted 6 years and entailed slow recruitment; inclusion of both VA and VV ECMO in the study analysis, suggesting a broad patient population, including combined cardiac failure; and lack of synchronization of institutional guidelines and protocols for ECMO management across 52 centers.

Goligher et al. reanalyzed the EOLIA trial data in favor of ECMO based on a Bayesian approach.[36] The analysis demonstrated that the trial was statistically flawed, and that by using Bayesian statistical analysis, a more nuanced understanding of the data was evident.

MECHANICS OF ECMO: CIRCUITS

ECMO includes insertion of peripheral and central cannulas. Central cannulation requires an incision in the chest, usually via sternotomy, to place the cannula in large central vessels. Usually, central cannulation is reserved for patients who are already cannulated for cardiopulmonary bypass for heart surgery and who fail to wean from bypass. The surgeon exchanges the cardiopulmonary bypass machine for an ECMO machine, utilizing the pre-existing cannula. Cannulating large central vessels allows the surgeon to insert very large device, allowing for higher flows.

Peripheral cannulation, which can be undertaken by non-surgeons, utilizes peripheral vessels for the ECMO cannula. Rarely, patients who require extremely high rates of flow may be switched from peripheral to central cannulation, but this is considered a highly morbid procedure due to higher bleeding and infection rates associated with central cannulation.[37,38]

Cannulas are named in relation to the ECMO machine. An *inflow cannula* drains venous blood *to the machine*, and an *outflow cannula* returns blood *to the patient* from the machine. As described below, outflow cannulas may return to an artery, vein, or both.

CHOICE OF ECMO PLATFORM

VV ECMO is the most common ECMO platform used for primary pulmonary failure.[39] One of the most common configurations for cannulation for ARF and ARDS is single-lumen, dual-site cannulation, with femoral vein inflow and right internal jugular (IJ) outflow (Fig. 149-2A).

The right common femoral vein (CFV) is the most commonly used access site for venous inflow due to the direct and linear anatomic configuration of the right common femoral vein as it transitions to the inferior vena cava towards the heart; however, the left common femoral vein may be accessed if the right common femoral vein cannot due to anatomic or structural abnormalities. The right IJ is suggested as the venous return location due to the short and linear approach to the right atrium. The left IJ is not ideal for venous outflow return because the left IJ turns acutely at the innominate confluence. The optimal position of the tip of the inflow cannula is at the inferior vena cava–atrial junction, which decreases risk of recirculation but allows for adequate drainage. The venous inflow drainage cannula is multi-orifice and, therefore, does not depend on rotational positioning to facilitate drainage. The venous outflow return cannula is usually an end-hole cannula. If placed near the orifice of the venous inflow cannula, recirculation can occur, particularly with higher rates of flow.[40]

A second approach to VV ECMO is insertion of a dual-lumen cannula via the right IJ vein. The dual-lumen single cannula (DLSC) encompasses three areas of blood flow: proximal, middle, and distal (Fig. 149-2B). The proximal and distal aspects of the cannula are multi-orifice drainage sites connected via a common blood-flow channel. The channel constitutes the venous drainage inflow component of the DLSC. The distal tip of the DLSC is strategically

placed into the inferior vena cava (IVC), and the proximal section of the DLSC is placed in the superior vena cava. The middle channel serves as the return outflow channel and rests in the right atrium facing the tricuspid valve.

The DLSC catheter should be placed using transesophageal echocardiography with assistance of fluoroscopic guidance to reduce the risk of right ventricle perforation.[41–43] Echocardiographic positioning is helpful in positioning the cannula so that the return outflow jet is directed towards the tricuspid valve.[44] Newer cannula designs are less dependent on rotational positioning for the outflow limb due to multi-orifice return channeling. Regardless, correct directionality of blood flow can be demonstrated on color doppler imaging of the bicaval or modified bicaval view on TEE.[45,46] The dual-lumen cannula keeps the groin vessels free of cannulas and enables the patient's participation in ambulation and physical therapy. Additionally, it does not sacrifice two venous access points, which are often scarce in critically ill patients in the ICU who need access for administration of vasoactive medications and, potentially, hemodialysis. Specific complications of this catheter strategy include difficulty in placement, lower potential flow range, cannula movement, cerebral venous congestion, and air embolism.

A third cannulation strategy is bifemoral (Fem–Fem) venous cannulation. This is usually considered a bridging or salvage cannulation configuration. If a patient is on femoral–IJ cannulation and needs to be transitioned to a dual-lumen cannula, femoral–femoral VV ECMO can be implemented so that a IJ cannula can be replaced with the dual-lumen cannula in the IJ position. Alternatively, a Fem–Fem strategy can be employed when femoral–IJ cannulation is not possible due to line infection, necessitating movement of catheters to new locations, or when no alternative venous access options remain. This strategy makes it challenging to mobilize the patient for physical therapy and carries a very high rate of lower extremity edema and DVT.[47,48] Furthermore, patients managed with a Fem–Fem cannulation strategy also have a high incidence of recirculation due to the proximity of the inflow and outflow cannula orifices.[49]

An advanced VV ECMO modality that can be considered in the setting of right heart failure with pulmonary failure is an oxygenated RVAD. Recently, a new catheter has been introduced that is effectively a percutaneous right ventricular assist device that can be oxygenated[50] (Fig. 149-3). This catheter-based approach is, in design, very similar to the DLSC; however, instead of having the inflow drainage positioned in the SVC and IVC, this cannula has a series of inflow orifices that are positioned in the superior vena cava and right atrium. The oxygenated outflow blood is then introduced distally in the pulmonary artery through a separate lumen.

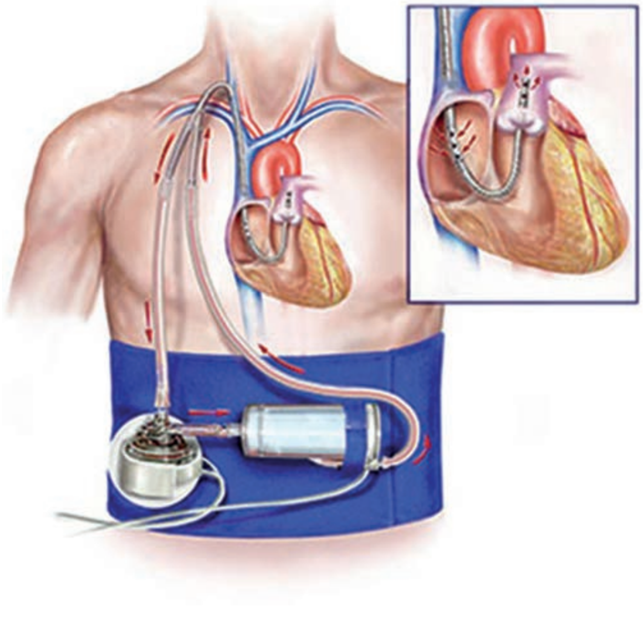

Figure 149-3 RVAD ECMO-Protek Duo.

To place this cannula, a pulmonary artery flotation (Swan-Ganz) catheter is first inserted into the main pulmonary artery (PA). A wire is exchanged through the catheter, and a DLSC Protek cannula is placed. The catheter is located in the same trajectory as a typical pulmonary artery catheter; however, it terminates in the main PA. Echocardiographic guidance is essential for ensuring placement of the catheter tip in the main pulmonary artery, as opposed to the right or left PA. Fluoroscopy is also essential for safety purposes, and placement of a stiff guidewire, into the middle or lower lobar pulmonary arteries is necessary to guide the catheter into place. The final location of the catheter tip is the distal main PA. Deep placement of the catheter into the right or left PA will result in severe ventilation–perfusion mismatching, hyperemia of one lung, and, possibly, pulmonary overcirculation.[51,52]

This cannula traverses both the tricuspid valve and pulmonic valves. The venous inflow drainage orifice drains blood from the SVC and right atrium, and the return outflow terminates as an end-hole at the tip of the cannula in the PA. This cannula is not always used with an ECMO circuit; originally, it was designed to be a percutaneous right ventricular assist device used with a centrifugal pump for isolated RV systolic failure. However, more common now is introduction of an oxygenator after the pump head to convert the cannula into an oxygenated RVAD.[53,54] This configuration not only provides oxygenation support, but also provides critical right ventricular support in a subset of patients with ARDS and RV systolic failure. In ARDS-induced cardiac failure, patients may have isolated RV systolic failure due to a myriad of causes, including ventilator-induced lung injury and cardiac dysfunction due to hypoxia, which often goes together with ARF.[54–56]

Although not considered a conventional ARDS and ARF modality, VA ECMO is also a platform that can be used for ARF (Fig. 149-2C). This modality is often considered when acute decompensated heart failure accompanies ARF.[55,57] Point-of-care transesophageal echocardiography is helpful in decision-making during evaluation for ECMO cannulation for ARF.[58] Prior to ECMO, a comprehensive echocardiographic examination can help diagnose a reversible etiology, as well as guide the cannulation strategy. If echocardiography demonstrates cor pulmonale, then VA ECMO or VAV ECMO might be indicated. Furthermore, pericardial effusions and LV function can be assessed, as well as valvular pathology, which may preclude VV ECMO cannulation.

Sepsis-induced heart failure in pneumonia with ARDS is a known phenomenon and occurs in up to 15% to 20% of patients.[59,60] When a patient is cannulated for ARF, a TEE examination can be used to predict the likelihood of success with isolated pulmonary support through VV ECMO.[45,58,61] If there is evidence of RV dysfunction, an oxygenated RVAD can be considered. If there is evidence of LV failure or biventricular failure with ARF and hypoxemia, then a VA ECMO or VAV ECMO cannulation strategy may be considered (Fig. 149-4). Additionally, in rare situations, patients who are on the brink of cardiovascular collapse may not tolerate VV ECMO cannulation; VA ECMO can be used as a rescue maneuver for concurrent heart failure and acute respiratory failure.[62,63] A VA ECMO system will help unload the RV and provide LV support and systemic oxygenation and may need to be used as a temporizing measure.

Once VA ECMO is established and the cardiac function starts to recover, a transition to VAV ECMO to partially support the heart, can be used in order to bridge the patient back to VV ECMO.[62] VAV ECMO is configured with an oxygenated venous outflow limb can be added to the right IJ, thereby splitting flow back to the patient

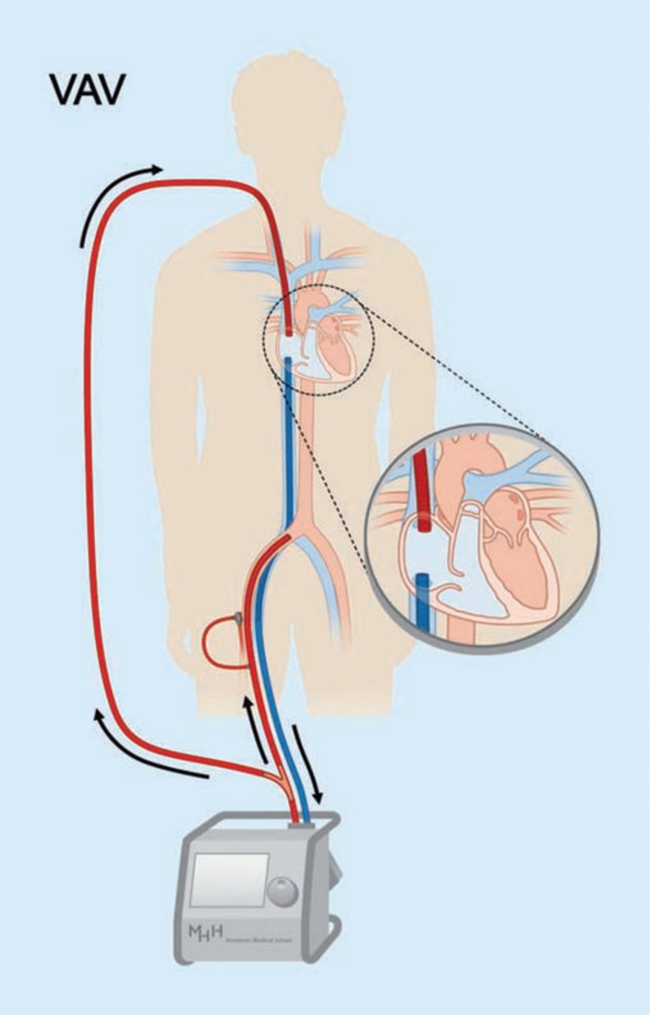

Figure 149-4 Veno-arterio-venous cannulation.

between the arterial and venous systems, which must be regulated by partially clamping the venous outflow limb. As LV support requirements decrease, more flow can be shunted toward the right IJ, and the arterial limb can eventually be clamped and decannulated while the patient recovers from respiratory failure; the patient can be converted to a traditional IJ/Femoral VV ECMO setup.

Patients with severe ARDS placed on peripheral veno-arterial ECMO are at high risk for continued hypoxia. The cannula do not completely empty the heart; thus hypoxic blood is usually ejected and delivers hypoxic blood to the coronary circulation and potentially the aortic arch (Fig. 149-5). If a patient with severe ARDS is placed on peripheral veno-arterial ECMO, every effort should be made to optimize pulmonary gas exchange to prevent differential hypoxia. Other maneuvers to prevent differential hypoxia include conversion to VAV ECMO to oxygenate blood that circulates through the heart or converting to central VA ECMO platforms such as the so-called sport model (Fig. 149-6).

Inclusion and Exclusion Criteria for ECMO

ECMO remains a limited resource that is associated with high costs and resource utilization.[28,64] It is prudent for hospitals and health systems performing ECMO to develop inclusion and exclusion criteria, which should be regularly reviewed.[33,65,66] Criteria for patients considered as a bridge to transplant may be more conservative than patients considered for ECMO as a bridge to survival.[67,68] Criteria have been published and utilized by the Extracorporeal Life Support Organization and by various ECMO programs (Table 149-1).[69,70]

RISKS OF ECMO

ECMO is a support tool, not a therapeutic tool. The technique carries several drawbacks, including need for large-bore vessel cannulation, infection associated with the cannulas, variable and erratic pharmacodynamics and kinetics of drugs (in particular, antibiotics), and need for anticoagulation.[71–73] Due to these risks, patients may experience severe complications, including strokes, severe bleeding, disseminated intravascular coagulation, deep venous thrombosis,

TABLE 149-1 Veno-Venous ECMO Criteria Example

Veno-Venous (VV) ECMO Indications	VV-ECMO Contraindications	VV-ECMO Relative Contraindications
$\mathrm{Pa}_{\mathrm{O}_2}$ <80 on $\mathrm{F}_{\mathrm{IO}_2}$ 100% *or* pH <7.2 with hypercarbia unresponsive to conventional management	Age >70 (except s/p lung transplant)	Weight >140 kg
Severe pneumonia	Severe cardiac insufficiency or cardiac arrest	Severe baseline disability (significant dementia, quadriplegia, etc.) that would inhibit ventilator weaning/rehabilitation
Acute respiratory distress syndrome	Nonrecoverable neurologic injury (ischemic, hemorrhagic, or anoxic)	
Graft failure following lung transplantation	Active malignancy with predicted survival <1 year	
Pulmonary contusion	Graft-vs.-host disease (post-allogeneic transplant ARF)	
Alveolar proteinosis	Severe pulmonary hypertension with severe right ventricular dysfunction	
Airway trauma		Ventilator dependent >10 days
Status asthmaticus	Severe baseline disability (end-stage, which would inhibit ventilator weaning/rehabilitation)	
Airway obstruction		
Aspiration syndrome	Age >70 (except s/p lung transplant)	
Postoperative hypoxemia		

and right ventricular failure.[74–76] Therefore, ECMO should be considered as a rescue treatment when conventional therapy would likely lead to death. The three main indications for ECMO in respiratory failure are refractory hypoxemia, refractory hypercarbia, and need for rescue from injurious mechanical ventilation.

INITIATION OF ECMO

A number of factors must be considered in initiating ECMO, including the decision to perform cannulation; a variety of technical considerations; specifics regarding choice of cannulas, oxygenators, tubing, and pumps; and subsequent monitoring of patients, as discussed below.

■ Decision to Cannulate

Several factors should be assessed when deciding to place a patient on ECMO support. The potential risks and benefits should be weighed for each individual patient. The three key elements include timing, presence of reversible lung pathology, and lack of contraindications. Timing of ECMO is critical, as highlighted in each of the aforementioned clinical trials.[12,28,35,77] A strict cutoff of 7 days of MV was used in all of these studies.[28,35]

Little literature exists regarding the optimal timing for initiation of ECMO since, historically, ECMO has been considered a salvage therapy. As ECMO has become more commonplace, early intervention has played a key role in improved outcomes and survival. Importantly, however, evidence-based practice and utilization of the full armamentarium of ICU treatment modalities should be exhausted prior to instituting ECMO; these modalities include complete pharmacologic paralysis, early and targeted antibiotic usage, low-stretch lung protective ventilation, and prone positioning.[78]

Early intervention is essential in ARF, and identification of reversible causes paramount for achieving good outcomes in ARDS and ARF. In addition, differentiation among acute causes of respiratory failure, chronic irreversible lung disease, and acute-on-chronic pulmonary disease is essential when selecting appropriate candidates for ECMO. Typically, specialized centers have developed strict inclusion and exclusion criteria based on the Extracorporeal Life Support Organization (ELSO) recommendations.[69,70] Strict exclusion criteria include extreme age, nonreversible neurologic injury, active malignancy with predicted survival less than 1 year, prolonged ventilator dependency, lung disease not amenable to reversal that will prevent successful weaning, extreme obesity, and high risk for anticoagulation, including active intracranial hemorrhage. A few specific etiologies that are considered common indications for VV ECMO include ARDS secondary to infection, trauma, pancreatitis, primary graft dysfunction after lung transplant, pre–lung transplant ARF, acute pulmonary embolism, acute eosinophilic pneumonia, alveolar hemorrhage, chronic obstructive pulmonary disease exacerbation, severe asthmatic exacerbation, large bronchopleural fistula, and extremely difficult, high-risk airway for planned operative intervention.

Clinical parameters to consider prior to cannulation include vital signs; hemodynamic metrics; vasopressor requirements; ventilator settings; presence or absence of active infections; baseline imaging, including CT imaging of the chest and cardiac echocardiography; immunosuppression; and etiology of ARF. Ethical considerations include do-not-resuscitate and do-not-intubate orders, as well as planned use of ECMO as a bridge to recovery, bridge to transplant, bridge to decision, and bridge to palliation.

When evaluating ventilator use for patients being considered for ECMO therapy, the guiding principles include restoring adequate systemic oxygen by matching ventilation and perfusion and maintaining cardiac output. Use of pulmonary vasodilators, including nitric oxide or inhaled epoprostenol, and use of PEEP for recruitment are essential.[79–82] PEEP adjustment and recruitment maneuvers help improve V/Q matching. Unfortunately, both hypoxemia and extreme ventilator settings can lead to cardiac dysfunction.[83] ARDS also can independently cause cardiac dysfunction as well, in particular cor pulmonale and RV failure due to severe increases in PA pressures.[84] Particular attention in candidate selection should be direct toward right ventricular function and volume status. Patient positioning, presence of anemia, and metabolic rate of oxygen consumption also play important roles when deciding to place a patient on ECMO.

ARDS-associated cardiac dysfunction is similar to that found in septic shock. Often times the cause of ARDS is pneumonia, which can cause septic shock and lead to cardiac dysfunction; furthermore, ARDS is a contributor to inadequate myocardial oxygen delivery.[85] In spite of fully maximizing ventilation and perfusion to the lung, inadequate cardiac dysfunction leads to decreased oxygen delivery at the tissue level. Both Swan-Ganz catheter use and point-of-care transthoracic and transesophageal echocardiography can be used to assess and monitor cardiac function. Clinical trials using Swan-Ganz catheters in the ICU have demonstrated no significant benefit for morbidity or mortality; however, newer European guidelines suggest use of a thermodilution pulmonary artery catheter in patients with ARDS can improve fluid management and estimation of extravascular lung water.[86–88]

Due to the equivocal data surrounding Swan-Ganz catheters, their use has fallen out of favor in many ICUs; however, newer, continuous monitoring catheters can provide better more detailed information. These catheters are now being increasingly used.[88]

Vasopressor and inotropic support should be added or titrated to support cardiac function, as well as peripheral vasomotor tone. In addition, fluid management remains difficult prior to initiation of ECMO, as well as in management of ARF in general. The competing clinical goals of decreasing pulmonary edema while maintaining optimal cardiac output are challenging. Echocardiography-guided fluid management and inotropic support can improve overall mortality.[89] Furthermore, carefully considered antibiotic choices, inotropic support, ventilator management, and fluid management can lessen lung and cardiac injury.

Broadly, indications for ECMO include hypoxemia and hypercapnia. Further delineation of the ECMO modality best suited for the patient can be achieved by evaluating cardiac function. If a patient with normal cardiac function has hypercapnia without hypoxemia, or hypercapnia with hypoxemia that is manageable using low-stretch, conventional ventilator settings, consideration should be given to low-flow venovenous ECMO. Alternatively, in the era of COVID-19 ARDS some physicians are utilizing minimally invasive ECCO$_2$R devices, which can remove carbon dioxide. These machines function with low blood flows and cannot improve oxygenation. If a patient has hypoxemia with normal cardiac function, the primary cannulation strategy is VV ECMO; however, if a TEE exam demonstrates RV, LV, or biventricular failure, cardiopulmonary support using advanced mechanical circulatory support should be considered, for example, oxygenated RVAD or VA ECMO (Fig. 149-7).

■ Technical Considerations

Both anatomic and physiologic principles are considered in determining cannulation location, configuration, and sizing. Additionally, consideration must be given to whether a patient needs to be stabilized with VV ECMO prior to, or after, transportation to higher level of care.[90]

VV ECMO flows are limited by venous cannula size, transmembrane pressure levels (knows as the *pressure drop*), and outflow cannula size. Insufficient cannula size may result in inadvertent

Figure 149-7 Decision algorithm for cannulation type.

hypoxemia if the ECMO circuit is unable to keep up with the native cardiac output[25,50] (Fig. 149-8). Flow limitation is often due to insufficient uptake of venous blood into the ECMO circuit; under these circumstances, a second drainage cannula can be placed. An additional consideration when choosing cannula sizing is minimization of the shearing effects on blood due to turbulence.[91] Use of larger cannulae, fewer connections, and less reliance on Luer lock connections result in less hemolysis.[25] Finally, cannulas with coated surfaces have been designed to prevent clotting and minimize activation of the coagulation cascade.

Patient height and weight should be used to calculate the body surface area (BSA) and estimate flow rates needed to provide

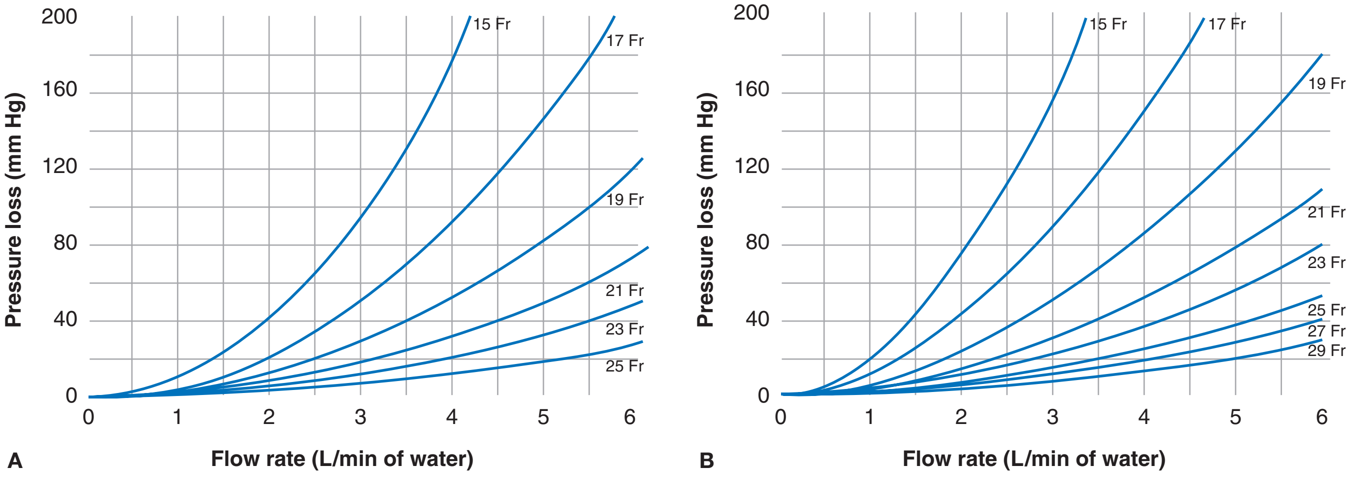

Figure 149-8 Example flow diagram for flow characteristics of cannula.

adequate oxygenation. An important anatomic consideration is body habitus, which may preclude patients from undergoing VV ECMO. Large pannus, excessive abdominal hypertension, or obesity may cause venous inflow obstruction and inadequate flow. Abdominal compartment syndrome is a relative contraindication for venous drainage cannulation.

The venous architecture and anatomy also should be considered when cannulating the patient. Patients often have limited venous access due to deep venous thrombosis or infection, further limiting options for VV ECMO cannulation. Cannulation configurations and tools are available to help address these constraints.

It is imperative to know the venous anatomy prior to cannulation, including whether an IVC filter is present; additionally, a persistent left superior vena cava or, rarely, a duplicated IVC should be considered.

A special subpopulation includes pregnant women. A large gravid uterus necessitates extra care in cannulating; a 10-degree left lateral tilt can be employed to free up the right femoral vein to iliac vein system.[92]

In order to select the correct cannula size, first priority should be given to titrating cannula size to estimated cardiac output requirements.[91] Peak flow through a cannula can be ascertained using information provided by the manufacturer in the instructions for use (IFU). An alternative method is to place maximum-sized cannulas based on vessel diameter measured on ultrasound during precannulation imaging. A balanced approach needs to be struck between the anticipated physiologic cardiac output through the course of the ECMO run (which is difficult to predict) and duration of ECMO (which can last days to weeks), and cannula oversizing (which can result in venous congestion, deep vein thrombosis, and vessel injury).

Several different cannulas are available for VV ECMO. VV cannulas are typically wire-reinforced with biocompatible polyurethane. Occasionally, the surface is coated with heparin to prevent clotting.[22–24,26] Currently, research is being conducted on use of nitric oxide released from ECMO tubing, circuit components, and cannulae to prevent or severely limit clotting.[93] Venous inflow cannula sizes range from 13 to 31 French, while venous outflow cannula sizes range from 13 to 21 French. The venous outflow cannula is typically an end-hole catheter.

■ Cannulas, Oxygenators, Tubing, and Pumps

The most important feature of a good ECMO circuit is simplicity, which makes ECMO easy to deploy at the bedside and defines the most powerful attribute of ECMO as a clinical tool.

The ECMO circuit is typically made of polyvinyl chloride plastic tubing with various connections, including a pump and oxygenator.[94] Connections, entry, and exit points are kept to a minimum to ensure sterility, to decrease the risk of air embolism, and to reduce the drag effect and thrombotic risk of edges and eddy currents. All ECMO circuits should be designed to minimize tubing length and transition points. The sizing of ECMO tubing determines the blood flow rate that can traverse a distance of 1 m with a pressure gradient of 100 mm Hg: 3/16-inch tubing accommodates flow at 1.2 L/min, 1/4-inch tubing at 2.5 L/min, 3/8-inch tubing at 5 L/min, and 1/2-inch tubing at 10 L/min.[95] Typically, 3/8-inch tubing is used.[91]

Not only does tubing diameter play a role in determining flow rates, but tubing length and size are important due to the biologic and pharmacologic effects of the tubing. Long tubing length exposes the blood stream to a large foreign surface, activating the inflammatory cascade and consuming vital clotting factors, while paradoxically increasing the thrombotic risk.[96–98] The large surface area of the tubing also alters the pharmacokinetics of several antibiotics, narcotics, and sedatives. As mentioned previously, during initiation of VV ECMO, the large prime volume can also contribute to acute hemodilution when the fluid is circulated during initiation. Blood priming can help augment those effects; however, blood priming may come with a risk of allosensitization if a patient with a high lung allocation score is placed on VV ECMO as a bridge to transplant.[99,100]

Typical ECMO pumps are driven by centrifugal force (Fig. 149-9). Centrifugal pumps use a magnetically levitated disc with inlet holes for blood and a common outlet for egress of blood. An external magnetic force is applied, causing the internal disc to rotate, raising the velocity, and creating a vortex of blood.[101,102] The centrifugal pump, much like an LVAD, is preload-dependent and afterload-sensitive. Flows fluctuate based on these two parameters and, therefore, no specific RPM provides the same amount of flow.

After leaving the centrifugal pump, blood enters an oxygenator. As described previously, the oxygenator is constructed using thousands of highly permeable tubes through which oxygen flows. Blood enters an interstitial-like space in which red blood cells float between the microtubules of gas. Oxygen enters blood plasma and red blood cells by diffusing down a concentration gradient. In a human lung, alveolar surface area is about 143 m^2, and capillary surface area is approximately 91 to 118 m^2. In a typical ECMO oxygenator, the surface area for gas exchange is 2 m^2.[103,104] Furthermore, the diffusion thickness from gas flow to blood surface is typically 100 μm, while in the human lung it is 2.2 μm[104] (Fig. 149-10).

A membrane oxygenator has functional limitations. The oxygenator is very efficient at CO_2 removal, and complete CO_2 removal can be accomplished using high-sweep gas flows and blood flow rates below 1 L/min. The addition of O_2 into the red blood cell, however, requires larger ECMO flow rates.[105–107] In order to achieve the O_2 delivery (DO_2) requirements for a typical patient (generally estimated to be 260 mL O_2/min) and a post-oxygenator O_2 gas tension >300 mm Hg, approximately 4 L/min flow must be maintained.[91] While blood traverses the oxygenator membrane, a large amount of heat loss occurs. Therefore, ECMO oxygenators also are required to provide heat exchange as blood crosses the membrane.[91]

Pre- and postmembrane pressure sensors allow for monitoring of oxygenator function, in addition to monitoring post-oxygenator gas values. A typical pressure drop across an oxygenator should not be >30 mm Hg, with an inlet pressure of 250 mm Hg and outlet pressure of 220 mm Hg.[108] Flow monitoring, as well as calculation of transmembrane pressure drop, is considered standard of care. Flow monitoring has been shown to be effective in identifying complications in the ECMO circuit and is easily incorporated in current ECMO practice. Since flow monitoring is continuous, it has the potential to serve as a nonspecific initial warning of elevated distal resistance.[108]

■ Spectrum Monitoring of ECMO Circuits

Future directions in ECMO circuit technology include advanced monitoring, such as that provided by integrated EMR systems like Spectrum (Spectrum Medical, Cheltenham, England).[109] Spectrum monitoring includes monitoring for continuous DO_2 and VO_2 by sampling pre- and post-oxygenator gas, monitoring for pressure drops, and subsequent integration of the information over time to synchronize with EMR systems. This capacity has not yet been fully integrated in all hospital systems. However, spectrum monitoring may provide real-time information and the potential to close loop circuits, thereby enabling automatic titration of flows and RPMs based on patient preload, afterload, and desired Pa_{O_2}.[110,111]

MAINTENANCE OF ECMO

Once initiated, the patient on ECMO must be carefully monitored using a variety of clinical approaches, as discussed below.

■ Machine and Cannula Maintenance

The ideal ECMO system provides a platform for CO_2 removal, addition of O_2 to the blood stream, minimal flow rates, and minimal risk

of bleeding or thrombosis. Additional extracorporeal components can be added, including continuous renal replacement and temperature management (heater/cooler) devices.

Several iterations of the oxygenators have been developed, including a silicone rubber membrane with molecular diffusion, as well as the PMP membrane oxygenator. Oxygenator lifespan and maintenance include provision of adequate anticoagulation and daily assessment of clot burden on pre- and post-oxygenator surfaces. The assessment can be performed with daily transillumination, as well as physical inspection of the oxygenator.

Optimally, standard ECMO configurations include transmembrane pressure monitors. If transmembrane pressures are noted to rise along with hemolysis laboratory values (e.g., lactate dehydrogenase, plasma free hemoglobin, fibrin split products), or if fibrinogen levels fall and platelets consumed, oxygenator or circuit exchanges may be necessary. Commonly, oxygenators are changed on a weekly or monthly timeframe, consistent with the natural lifespan of the device.

Routine arterial and venous blood gas monitoring is mandatory for patients on VV ECMO. Patients on VV ECMO should have an arterial line in place for frequent hemodynamic and laboratory monitoring, as well as central line for vasoactive medication administration. Post-oxygenator Pa_{O_2} blood gas monitoring can help identify failing oxygenators. Establishing institutional practice guidelines for thresholds in oxygenator exchanges based on tolerated post-oxygenator Pa_{O_2} levels should be done. Post-oxygenator Pa_{O_2} should be checked at 100% ECMO FI_{O_2} and can be done at other FI_{O_2} settings as well. "ΔCO_2" levels should be calculated by comparing venous gas P_{CO_2} with post-oxygenator gas P_{CO_2}. ΔCO_2 levels can be used to assess the status of the oxygenator's CO_2 removal capacity,

as well as patient readiness for decannulation or need to transition to $ECCO_2R$ devices if available.

The pump head and cannulas should be assessed for function and presence of clot daily. A spare manual, hand crank–driven centrifugal pump should be available on the ECMO cart in case of acute pump thrombosis or failure. Daily chest radiographs are mandatory to confirm cannula position. Cannulas often can migrate, especially during patient transport or prone positioning, and inadvertent decannulation can be catastrophic. Cannulation sites should be checked for induration, erythema, and evidence of infection, as well as wound development. Daily management of the ECMO machine and circuit is an essential aspect in the care of patients.

■ Ventilator Management

Very little definitive literature has been published regarding ventilator management for patients on VV ECMO. There is a complex interplay among the patient, the ECMO circuit, and the ventilator. Generally, lung protective ventilation using low tidal volumes is a cornerstone of management in ARDS.[112,113] This was demonstrated by Amato et al., who detailed the effects of a protective-ventilation strategy on mortality. They demonstrated that massive alveolar collapse, cyclical lung reopening, and overdistention during mechanical ventilation perpetuates alveolar injury: so-called ventilator-induced lung injury. This randomized control trial demonstrated improved survival at 28 days using protective tidal volumes of 6 mL/kg and driving pressures $<$20 cm H_2O.[114]

When a strategy of protective ventilation of 6 mL/kg is impossible due to the severity of lung disease and refractory hypoxemia, VV ECMO can be used to avoid ventilator-induced lung injury.[115,116] By using ECMO as a bridge, ventilator settings can be adjusted to avoid volutrauma, decrease set ventilator respiratory rate, decreasing repetitive inflation–deflation injury, and improve oxygenation, thereby improving cardiac and other organ functions. This strategy is known as "ECMO lung rest."[115,117] Unfortunately, the optimal ventilator strategy in patients with severe acute ARDS supported with VV ECMO has not been delineated.[118,119] Further complicating the complexity of ventilator management during VV ECMO is the fact that the terminology is not standardized. The question remains: to which new ventilator lung protective settings should the patient on VV ECMO be transitioned?

Individual elements of the ventilator can be modified during VV ECMO, including tidal volume, respiratory rate, FI_{O_2}, and level of PEEP. Pressure control ventilation (PCV) and volume control ventilation (VCV) settings have been used for patients on VV ECMO, as have spontaneous modes, such as pressure support ventilation (PSV).[120] While on VV ECMO, a tidal volume below 6 mL/kg can be achieved, resulting in near-absent tidal stress and strain. As noted previously, decreasing the intensity of mechanical ventilation beyond simply achieving tidal volumes 4 to 6 mL/kg predicted body weight (PBW) is associated with improved survival in patients with ARDS.[30] Depending on the severity of the underlying lung injury and subsequent impairment in respiratory system compliance, the tidal volume achieved using PCV may be very small. With high-flow VV ECMO, tidal volumes can potentially be brought to zero, constituting a strategy called "total lung rest."[115,121]

One potential benefit of using PCV during VV ECMO is that with a constant driving pressure, larger tidal volumes may be observed as the patient's condition and respiratory system compliance improves. This may signal a readiness for sedation weaning and decannulation.

The ventilator settings used in the CESAR trial were PCV with a peak inspiratory pressure limited to 20 cm H_2O, a PEEP of 10 cm H_2O, a respiratory rate of 10 breaths per minute, and an FI_{O_2} 30%.[28] In the EOLIA trial the ventilator settings were a plateau pressure $\leq$24 cm H_2O, PEEP $\geq$10 cm H_2O, respiratory rate of 10 to 30, and FI_{O_2} of 30% to 50%.[35] This lung rest strategy targets decreased respiratory rate, decreased tidal volume, and fixed PEEP and driving pressures. The drawbacks of this strategy remain severe alveolar derecruitment and irreversible lung consolidation. Complete atelectasis and fibrosis of lungs may occur. However, this remains the most commonly used MV strategy during VV ECMO.[118]

While data from large clinical trials supporting "ultraprotective" ventilatory settings are lacking, these settings are a logical extrapolation from established principles aimed at minimizing ventilator-induced lung injury and maximizing survival and are of increasing research interest. Further research is needed to determine whether putting the lung completely at rest could be a better solution than providing any ventilation on top of a continuous pressure. Likewise, extubation to spontaneous breathing, or the use of noninvasive ventilation such as BiPAP, CPAP, or high-flow nasal cannula (HFNC), while the patient is receiving VV ECMO for ARDS, is also an area of uncertainty at present.[122–124]

The optimal settings for PEEP for a patient on VV ECMO are also a matter of debate. Some groups use a higher PEEP (>10 cm H_2O), leveraging a strategy that keeps alveoli open and prevents atelectasis, while other groups use a strategy that includes no PEEP and negative-pressure ventilation.[118] Excessive use of PEEP may result in alveolar overdistention with increased plateau pressure and driving pressures. If no alveolar recruitment occurs, then the patient does not benefit (no improvement in oxygenation). Additionally, high levels of PEEP can result in cardiac dysfunction and decreased venous return.[125]

Investigators have demonstrated that high levels of PEEP may be associated with improved survival.[66] A high-PEEP/low-tidal-volume strategy while using VV ECMO is called the "open-lung approach."[126] The open-lung approach has not been clinically validated to produce better outcomes; rather, the strategy is based on mitigation of known causes of secondary lung injury in ARF and ventilator-induced injury, in particular, alveolar collapse and strain.[127–129] Generally, in VV ECMO, PEEP-related alveolar recruitment is less frequently required to improve oxygenation or to reduce the impact of regional alveolar stress and strain; however, when combined with an open-lung strategy, recruitment maneuvers have failed to demonstrate survival benefit.[130]

Nonpulmonary gas exchange provided by the ECMO circuit must be sufficient to enable avoidance of injurious levels of mechanical ventilation. At a minimum, the MV settings should not exceed evidence-based guidelines. Generally, clinicians should target a plateau pressure ≤ 30 cm H_2O and tidal volume of 4 to 6 mL/kg predicted body weight, as used in patients with ARDS who are not supported with VV ECMO.[131,132] However, in many cases of VV ECMO, ventilatory settings can and, likely, should be set considerably lower than these thresholds, particularly driving pressure (e.g., <15 cm H_2O, keeping inspiratory Pplat <25 cm H_2O) and respiratory rate (e.g., 4–15 breaths/min). Any mode that can achieve lung-protective ventilation (e.g., PCV, VCV, APRV, neurally adjusted ventilatory assist [NAVA]) can be used. Once the patient stabilizes and sedation is lightened, transitioning to spontaneous breathing on partial-assist modes (e.g., pressure support ventilation) should be considered.

In a recent, large observational study involving patients treated with VV ECMO for H1N1-associated ARDS, the plateau pressure observed during mechanical ventilation while the patient was supported with VV ECMO was found to be a significant prognostic factor.[30] Plateau pressure and compliance before initiation of VV ECMO were not significantly correlated with prognosis, suggesting that plateau pressure while on VV ECMO was nothing more than a simple marker of severity. These data were used to design the ventilatory strategy used in the EOLIA trial, using a plateau pressure strictly <25 cm H_2O while the patient was supported with VV ECMO.[35,125] Finally, because lung protection remains an important objective during VV ECMO, not only a low plateau pressure, but also a low respiratory rate, may be recommended.

■ ECMO Management

VV ECMO provides the patient with a fixed quantity of oxygen, based on circuit flow and blood oxygen content. The total oxygen content of blood (Ca_{O_2}) is determined as $Ca_{O_2} = [\text{Hemoglobin}] \times 1.36[Sa_{O_2}] + 0.0034[Pa_{O_2}]$. Since the vast majority of oxygen in blood is bound to hemoglobin, the final arterial oxygen saturation of blood returning from the ECMO circuit has an oxygen saturation of 100%. However, ECMO does not drain all venous return to the heart, so a percentage of the patient's cardiac output shunts past the ECMO circuit (e.g., that coming from the coronary sinus). The concentration of oxygen in the pulmonary artery is dependent on the weighted average of the saturations of venous blood bypassing the ECMO circuit and the fully saturated ECMO blood flow. This can be defined as the ratio of ECMO blood flow to cardiac output (ECMOBF/CO).

Once the blood enters the pulmonary artery, it passes through the pulmonary circulation, and based on the injured lung's ability to oxygenate and remove CO_2, the final P_{O_2} in arterial blood is determined. If any native lung function remains, the Pa_{O_2} rises. If there is a complete shunt, the final Pa_{O_2} will be equivalent to the Pa_{O_2} in the PA. Once blood enters the systemic arteries, hemoglobin concentration and cardiac output determine O_2 delivery, as described by the previously noted equation for Ca_{O_2}. Therefore, a balance between HR and RV filling, and ECMOBF/CO and left sided cardiac output and O_2 delivery, is important in determining tissue oxygenation.[133]

Two important clinical considerations should be anticipated during the initiation and maintenance phases of VV ECMO. First, during the initial circulation of VV ECMO, exposure to the plastic tubing, oxygenator, and machinery causes a profound vasodilation that can increase the cardiac output by reducing the afterload.[134] Second, the ECMO circuit prime volume, which can vary based on tubing length, results in acute hemodilution. When the ECMO circuit initially starts to circulate, it can cause a decrease in oxygen saturation if the VV ECMO flow rate is kept static.[135] In order to counteract this initial vasodilation, an increase flow rate is recommended to maintain saturations greater than 92%. Additionally, liberal use of vasopressors should be considered. Pretreatment with vasopressors or push-dose vasopressors should be on hand when initiating VV ECMO. Additionally, the temperature difference between the blood and crystalloid prime can cause profound bradycardia.

If the initial indication for VV ECMO is acute respiratory failure secondary to infection, sepsis, pneumonia, or shock, and cardiac output is high, setting the ECMO flow rate to a normal cardiac output may cause hypoxemia due to a reduced ECMOBF/CO ratio. Likewise, during a long ECMO run, if the cardiac output increases due to any cause (e.g., infection, sepsis, sedation weaning) and lung function remains compromised, the patient may experience hypoxemia due to shunt. For example, consider circumstances in which the VV ECMO flow rate is set at 5 L/min and the native CO increases to 10 L/min. If the ability of the damaged lung to oxygenate remains unchanged, then even in the setting of 100% saturation from the ECMO circuit, the native lung needs to provide $>80\%$ saturation to maintain a final saturation of 90% in the systemic circulation (barring any shunts or venous admixture). V/Q mismatch and shunts will further decrease the final systemic saturation. Therefore, preload, cardiac output, ECMO flow rate, and hemoglobin levels need to be managed closely during VV ECMO.

After patient stabilization on VV ECMO, and with recovery of cardiac function and improvement in tissue oxygenation and waste removal, vasoactive support can often be reduced significantly. Hemodynamic goals should be reviewed daily and adjusted, if necessary. In general, a fluid-restrictive approach to volume resuscitation is promoted after the acute phase of critical illness to avoid excessive capillary leak and improve pulmonary function. A restrictive transfusion practice also may be considered, targeting a hemoglobin threshold >7 g/dL.[136,137] In patients with a high cardiac output due to sepsis or other cause, significant hypoxemia can occur due to excessive blood flow through the native lungs.[138] A trial of short-acting beta-blocker infusion may be an effective method to improve oxygenation by reducing the patient's native cardiac output, reducing pulmonary shunt, and increasing the fraction of blood flow through the ECMO circuit.[133]

Fluid Management

Many patients undergoing invasive mechanical ventilation for severe respiratory failure are in a vasoconstricted state and demonstrate impaired peripheral perfusion. Fluid administration frequently causes some pulmonary edema, especially during inflammatory states, which then impairs gas exchange. Thus, many patients with severe respiratory failure are managed with a fluid-restrictive strategy before initiation of VV ECMO, in part because a conservative fluid strategy in patients with ARDS is associated with improved outcomes.[139]

ECMO, like any mechanical circulatory support device, is preload dependent; therefore, the ability of the ECMO circuit to oxygenate blood is dependent on the ECMO blood flow through it. Increasing blood flow during VV ECMO predictably increases systemic oxygen delivery. When patients are initially placed on ECMO, the goals for fluid resuscitation should be targeted toward maintaining adequate flows, appropriate preload, and sufficient volume for the ECMO circuit to run effectively. This initial phase of fluid administration may result in an increase in pulmonary edema. During this resuscitative phase, lung compliance decreases; at stable inspiratory pressures, tidal volumes rapidly and predictably fall. There is evidence to suggest that MV changes to overcome this decrease in tidal volume should not be undertaken. Increases in ventilatory intensity to overcome the decreased compliance seem more injurious than beneficial, assuming adequate ECMO flow and systemic oxygen delivery.[140] This is especially true with ECMO initiated for SARS-CoV-2–related ARDS. Therefore, decreases in ventilation and tidal volume with increasing lung water during the resuscitative phase of VV ECMO should be tolerated by using ECMO flow to enable sufficient gas exchange.

Predictably, as the inflammatory process improves over the first few days and the lungs are not subjected to injurious ventilatory forces in an effort to "overcome" the pulmonary edema, the fluid is redistributed back into the vasculature. As tissue oxygenation improves and the inflammatory response abates, fluid removal and improvement in EVLW can be targeted. Over the maintenance phase of ECMO, negative fluid balance results in better lung compliance, while increased fluid balance results in increased mortality.[141–143]

Chatter and Suck-down

The venous drainage inflow cannula, typically positioned in the femoral vein, extends into the inferior vena cava, terminating at the cavoatrial junction. The cannula is usually fenestrated, with multiple side holes to optimize drainage. The centrifugal pump in the ECMO circuit creates negative pressures, ranging from 200 mm Hg to 250 mm Hg ("premembrane" pressure). Fluid balance during the ECMO run changes, depending on the goals of ICU management, for example, diuresis for the volume-overloaded patient versus provision of sufficient vascular volume to ensure adequate flow on ECMO. Intravascular venous volume, patient position, intrathoracic pressures, and cannula type all influence the tendency of the vein to collapse around the pre-pump cannula. This can be as minor as "chugging," during which the pre-pump limb demonstrates a low-frequency rhythmic "chatter," or more severe collapse, leading to deceasing ECMO flow or "suck-down." Excessive fluid administration to decrease suck-down events often leads to harmful fluid overload. Fluid management should be guided by the patient's condition and degree of pulmonary edema. The ideal treatment for persistent suck-down and severe chatter is to turn the ECMO flows down if the patient's oxygenation and ventilation status allow.

The DLSC has many of its return fenestrations on the sides; hence, the catheter typically is associated with more instances of intermittent flow limitation compared to a nonfenestrated cannula or one located in a dependent position, such as the femoral vein. In general, the flow limitations are more dramatic during rapid shifts of intrathoracic pressure, such as during coughing or when the patient is sitting up or ambulating.

As the patient improves, increases in intravascular volume are expected; resolution of capillary leak leads to fluid redistribution back into the vasculature, thereby facilitating diuresis. Under these circumstances, alternative causes of intravascular volume depletion should be considered, such as bleeding, which commonly occurs in patients on ECMO, and septic shock.

Systemic Inflammation and Fluid Resuscitation

Administration of intravenous fluid to patients experiencing an initial inflammatory vasodilatory state results in increases in systemic blood flow.[96] While the ECMO circuit provides a fixed quantity of oxygen to the body at a given level of ECMO blood flow, arterial saturation during ECMO is dependent upon the ratio of ECMO flow to systemic blood flow, which incorporates native lung function. Predictably, within the first few hours after initiation of ECMO, systemic saturation decreases. The decrease is likely related both to increases in lung water with fluid administration and corresponding impairment of gas exchange. Additionally, decreases in the ECMOBF/CO ratio, as systemic cardiac output increases with improved oxygenation, may contribute. To the extent that decreases in systemic saturation are due to changing flow ratios, peripheral oxygen delivery often remains unchanged or increases. It is critically important to ground assessments of adequate oxygenation on objective measures of tissue perfusion, rather than the percent saturation of arterial blood.

With improvement in the initial inflammatory state, increases in blood flow and oxygen delivery often lead to improvement in organ function and, in cases of preserved renal function, an autodiuresis.[96] Limited data are available in ECMO populations to guide fluid management after the initial resuscitative phase. Since a conservative fluid management strategy has shown benefit in patients with ARDS without ECMO, in the absence of data, it is reasonable to assume that following initial fluid resuscitation the same holds true for critically ill patients managed with ECMO.

In many of the studies that demonstrated a benefit with conservative fluid management in ARDS, fluid minimization commenced only during days 1 to 4, following an initial resuscitative phase. In some studies, diuretics were also administered to achieve this conservative fluid status.[144,145]

Evidence suggests that a negative fluid balance, including that attributed to deresuscitation, is associated with reduced mortality and shorter duration of mechanical ventilation for patients with ARDS, including patients on ECMO.[141,143] In two other studies of VA ECMO for shock, the highest quartiles of positive fluid balance were associated with increased mortality; patients with negative fluid balance demonstrated improved survival.[146,147] Increasingly, data from ECMO and non-ECMO patients suggest harm from excessive fluid administration and positive fluid balance. Thus, the best available data at this time suggests that after the initial resuscitative phase of VV ECMO, patients should undergo de-resuscitation to achieve negative fluid balance.

Anticoagulation and Bleeding in ECMO

Exposure of blood to the polyvinyl chloride, PMP, and oxygenator surfaces actives the thrombotic and inflammatory response systems. When blood proteins are exposed to the foreign surface of the polyvinyl chloride and PMP in the oxygenator, several activating factors, including von Willebrand factor (vWF), bind to the surfaces; platelets are activated, and fibrinogen is converted to fibrin that binds to the surface. Thrombin formation also creates a mesh network that consumes coagulation factors. Coagulation factors leak from plasma as blood is moved through the oxygenator, and proteins leak in a retrograde direction through the pores of the microtubules carrying oxygenated gas.

In addition, proinflammatory mechanisms that include neutrophils, monocytes, and leukocytes are activated—a process that occasionally becomes deranged, constituting "cytokine storm."

Anticoagulation at the time of initiation and maintenance is usually required during VV ECMO. Due to the anticoagulation requirement, as well as thrombocytopenia, mechanical destruction of platelets, and loss of clotting factors, patients on ECMO are at increased risk of bleeding. Additionally, heparin is used to bind to antithrombin III, which leads to decreased thrombin formation and decreased clot formation. Antithrombin III levels may also decline due to critical illness and losses during ECMO.[148] Hemorrhage also may be attributed to direct injuries during cannulation. However, with vascular access ultrasound, improved cannula design, better wire placement, and echocardiography guidance, hemorrhagic complications have been mitigated significantly.

In patients on ECMO, common sources of bleeding include epistaxis and gastrointestinal sources; rare sources include intracranial or pulmonary sources.[149] Anticoagulation protocols typically include intravenous unfractionated heparin; however, some institutions select bivalirudin or argatroban more often. The advantages of heparin include ease and familiarity of use, easy reversal, and easy monitoring with PTT and activated clotting time levels. The drawbacks include variable anticoagulant effects, heparin resistance, and heparin-induced thrombocytopenia. Direct thrombin inhibitors, including argatroban and bivalirudin, carry a lower risk of heparin-induced thrombocytopenia (HIT) and function independently of antithrombin III. However, they are renally and hepatically cleared and require adequate end-organ function. Unfortunately, there are no U.S. Food and Drug Administration–approved reversal agents for these intravenous direct thrombin inhibitors. Hemodialysis and activated factor VII are options. With normal renal and hepatic function, the half-lives range from 25 min for bivalirudin to 45 to 50 min for argatroban.

Recently, investigators performed a retrospective, single-center cohort study of patients on VV ECMO, 162 of whom received unfractionated heparin and 133 of whom received bivalirudin.[150] Patients on bivalirudin had decreased circuit thrombosis, increased time to circuit thrombosis, and decreased transfusion requirements for packed red blood cells, plasma, and platelets. Most importantly, they found. fewer major bleeding events for patients treated with bivalirudin than those treated with heparin (40.7% for patients receiving heparin vs. 11.7% for those receiving bivalirudin).[150]

Imaging

As with any invasive procedure, there are risks in establishing the ECMO circuit, including vascular injury. Common pitfalls include pneumothorax and arterial puncture or injury.

Percutaneous vascular access should be guided using linear surface ultrasound. Once vascular access is obtained, cardiac transesophageal echocardiography (TEE) should be performed prior to, and during, cannulation. TEE examination should include assessment of right and left ventricular function. Particular attention should be paid to the presence of a patent foramen ovale, atrial septal defect, or ventricular septal defect. The presence or absence of a pericardial effusion (likely transudative) should be noted.

Once cannulation is commenced, several passes of large, stiff wires may result in injury to the cardiac structures. The presence of a postprocedural pericardial fluid may suggest hemopericardium.[87] Other pathologies should not be ignored, including large pleural effusions, which can be readily seen on TEE. Finally, TEE should be done at the time of cannulation, as undiagnosed cardiac dysfunction may occur concurrently with ARF, prompting a change in cannulation strategy from VV ECMO to VA ECMO.

Although fluoroscopy and TEE can each be used to guide ECMO cannulation, since many cannulations have moved to the ICU setting, for both VA and VV ECMO, TEE, at a minimum, is required for cannulation. When necessary, fluoroscopy can be used when available in the cardiac catheterization laboratory or in the operating room.

Imaging using TEE is mandatory when placing the dual-lumen, bicaval Avalon cannula because the outflow jet should be directed towards the tricuspid valve. This can be determined using color doppler through the cannula orifice. TEE also should be used to confirm the distal positioning for a RA/PA Protek Duo cannula; the tip of the cannula should be situated in the main pulmonary artery, and color doppler should be directed bidirectionally into branch pulmonary arteries. Distal migration may result in V/Q mismatch.

Particular attention should be directed to the TEE when starting the circulation during ECMO. Initial exposure to the large volume of cold saline may result in cardiac bradyarrhythmias. During VV ECMO blood is taken from, and returned to, the right heart with no significant change in RV preload and no adverse effects on left-heart hemodynamics. VV ECMO also increases mixed venous oxygen saturation, leading to a decrease in pulmonary vascular resistance and a lower RV afterload. The increased oxygenation of the LV indirectly improves the LV function and increases oxygen delivery to the coronary artery circulation. During the ECMO run, patients should have frequent chest imaging, not only to monitor ARDS progress but also to closely monitor cannula positioning; daily chest radiographs are recommended. Furthermore, serial, lower extremity duplex venous scanning is essential to evaluate for DVTs.

Physical Therapy

Patients on ECMO may be safely mobilized for physical therapy (PT) and benefit from both PT and occupational therapy (OT). In a retrospective cohort study of 100 patients on ECMO, 35% participated in active physical therapy;[151] 19% of patients were on ECMO as a bridge to transplant and 16% as a bridge to recovery for ARDS. Patients were on ECMO for an average of 14 days and received an average of 7 PT sessions. During PT sessions, 51% of patients ambulated.[151]

Particular attention should be paid to the cannulation strategy when patient ambulation is anticipated. DLSC IJ cannulation is the ideal platform for ambulation, with or without mechanical ventilation. Furthermore, a portable ECMO machine, such as the Cardiohelp system by Marquet, constitutes a low-profile device with combined pump and oxygenator and is amenable to both patient transport and mobilization with PT.

DECANNULATION

Careful planning should be undertaken for patients who have clinically improved and are ready for decannulation, as described in the following sections.

Weaning ECMO

As with all ICU therapies, weaning and liberation from ECMO are clinically challenging and poorly studied. No gold standard approach exists; rather, several physiologically sound strategies have been advocated.

As a patient's lung function improves, typically compliance also improves while on low-stretch ventilation. The P/F ratio rises. Patients on ECMO for lung rest, who are on pressure control ventilation and have unchanged driving pressures, begin to manifest larger tidal volumes as lung healing occurs. During the recovery phase, sweep gas flow and F_{IO_2} on the VV ECMO circuit are independently weaned. If the patient presented has concurrent hypercarbia or demonstrates difficulty with CO_2 removal in the setting of stable oxygenation, then transition to $ECCO_2R$ can be undertaken. If the initial indication for VV ECMO was hypoxemic respiratory failure, then every attempt should be made to wean the ventilator first.

Patients can be extubated while on VV ECMO if mechanical ventilation is no longer necessary. Reaching the point of extubation is, however, not the most common scenario. Extubating patients while on VV ECMO is a challenge because the clinician needs to strike a balance between wakefulness and sedation/analgesia, allowing for appropriate respiratory drive in the setting of damaged neuropulmonary feedback due to ARDS. Awake patients on ECMO often demonstrate extreme tachypnea and coughing, which can cause a decrease in ECMO flow rates. However, awake, ambulatory, negative pressure–based ventilation while on VV ECMO is an ideal platform for lung rest and minimization of ventilator-induced lung injury.[152]

Frequently, patients require mechanical ventilation for longer periods than they require ECMO support. The risks and benefits of prolonged ECMO support versus decannulation must be considered in the setting of achieving minimal mechanical ventilatory support necessary to maintain oxygenation adequate for end-organ function. This is often the most common scenario in transitioning from ECMO. When the patient's ventilatory requirements can be met with MV alone, ECMO can be discontinued.

Basic weaning thresholds for decannulation include $\mathrm{FI_{O_2}}<50\%$, PEEP <10 cm H_2O, respiratory compliance >50 mL/cm H_2O, and respiratory rate <20 breaths per minute. Patients should be able to sustain these settings for at least 48 h. The airway should be cleared of all secretions and mucolytic therapies continued following decannulation. Patients should not have active pneumonia or other infections that would portend post-decannulation failure. Frequently, patients have had a tracheostomy and are debilitated from paralysis, immobilization, and fluid administration associated with treatments common in ARDS. Diaphragmatic failure can also result in post-decannulation respiratory failure. Anticipated increases in metabolic oxygen requirements, such as those due to fever, lightening sedation, and infection should be considered when deciding to decannulate.

Decannulation may result in a systemic inflammatory response syndrome (SIRS) as indwelling catheters are removed, as well as showering of clot and thromboembolism which can compromise lung function. If these effects are not anticipated, a decannulated patient may not be able to achieve adequate oxygenation or CO_2 removal with mechanical ventilation alone, thereby necessitating recannulation or patient/family discussion regarding failure of therapy and palliation.

Finally, the underlying lung pathology should be considered. An appropriate decannulation strategy should incorporate the ARDS pathology arc and the timing from onset of critical illness. Patients with acute-on-chronic lung failure, baseline interstitial lung disease or pulmonary fibrosis, or chronic obstructive pulmonary disease are extremely challenging and can pose difficulty in liberating from ECMO, necessitating a bridge to transplant or to palliation.

Stepwise reduction in $\mathrm{FI_{O_2}}$ on both the ventilator and VV ECMO circuit should take place incrementally. The VV ECMO circuit should be reduced to 21% O_2 concentration prior to decannulation for a period of 24 h or more. The patient should maintain a $\mathrm{Sa_{O_2}}$ $>92\%$ on this setting with a ventilator $\mathrm{FI_{O_2}}<50\%$. Similarly, the sweep gas should be reduced to 0.5 to 1 LPM. The $\mathrm{Pa_{CO_2}}$ should be <60 mm Hg, and a normal pH should be maintained for at least 24 h. Simultaneously, consideration should be taken for any metabolic alkalosis or acidosis that would require acute compensation by pulmonary mechanisms.

Respiratory failure after decannulation may occur if the patient requires an acute increase in minute ventilation due to metabolic acidosis that was unaccounted for at the time of decannulation. Some groups in Europe have described introduction of CO_2 into the circuit to challenge the respiratory system in CO_2 removal. However, this is not recommended, especially in critically ill patients. Weaning to hemolung may be a feasible option and is ideal when the sweep has reached 1 LPM and maximum flows of 0.5 LPM are required.

Particular attention around the time of decannulation should be directed to cannula-induced thrombus and acute pulmonary embolism during cannula removal. Anticoagulation should be stopped prior to decannulation, and serial arterial blood gases followed for 24 h post-decannulation.

Outcomes and Long-term Effects

The most recent international report (January 2018) from the Extracorporeal Life Support Organization (ELSO) Registry documented 15,686 ECMO runs in adults with respiratory failure; 66% survived the ECMO run and 59% survived to hospital discharge.[153] This report found that the most common diagnoses requiring VV ECMO support included ARDS due to viral pneumonia, bacterial pneumonia, other medical causes of ARDS, postoperative ARDS, and trauma-related ARDS.

In the prior 2016 ELSO Registry report, the ECMO average run duration for adult respiratory failure was 256 h for postoperative or trauma-related ARDS, 313 h for non-postoperative or non-trauma-related ARDS, 275 h for acute respiratory failure (non-ARDS), 261 h for bacterial pneumonia, and 325 h for viral pneumonia. Many patients required prolonged ECMO, defined as >14 days.

VV ECMO for adults with ARF represents the fastest growing use for any type of mechanical circulatory support or ECMO platform.[154] A small percentage of patients may not be successfully weaned and die on ECMO support, while an even smaller number go on to lung transplantation.[155]

Complications

As described previously, a number of complications are explicitly associated with ECMO, including bleeding, thromboembolism, infection, hemolysis, wound formation, and malnutrition. However, critically ill patients with ARDS receiving ECMO also undergo additional therapies such as prone positioning, which may be associated with complications, and long-duration paralytics, which may contribute to poor long-term quality of life.[156]

Survivors of ARDS experience limited functional capacity, decline in pulmonary function test results, and decreased 6-min walk testing at 6 months.[157] ARDS survivors at 1 year have been reported to have lost 18% of their baseline body weight at the time of ICU discharge.[158] Additionally, although lung and spirometric measures may be normal by 6 months, $\mathrm{DL_{CO}}$ is decreased, and distanced walked is reduced compared with predicted at both 3 months and 6 months.[158]

Not many long-term studies have been published in the setting of VV ECMO for ARDS post–ICU discharge. The assumption is that patients with ARDS managed with ECMO had worse baseline disease necessitating the use of ECMO and, therefore, survivors would be expected to have generally worse functional status compared to patients who survived ARDS who were not treated with ECMO.

In one study of a limited group of patients, 28% of ECMO survivors reported anxiety and 56% reported depression. These patients had a posttraumatic stress disorder response and a quality of life, when matched for age and gender, that was lower than that of conventional ARDS survivors.[169]

One of the most comprehensive follow-up studies of patients with ARDS managed with ECMO described the PRedicting dEath for SEvere ARDS on VV–ECMO (PRESERVE) score, which is a practical mortality tool to assess patients in the ICU. The investigators assessed 140 patients with ARDS who were treated with ECMO at 6 months. They found that 60% were alive. The PRESERVE class defined parameters of age, BMI, immunocompromised state, prone positioning, days of mechanical ventilation, sepsis-related organ failure, plateau pressure, and PEEP. Six-month survival was scored as 97% for patients with 0 to 2 factors, 79% for those with 3 or 4 factors, and 54% for those with 5 or 6 factors. Anxiety, depression, and PTSD were reported in 34%, 25% and 16% of patients, respectively.[160]

Wound Care

Vascular complications from large bore cannulation result from a long duration of cannulation, the high risk of infection, and obstruction to native blood flow which promotes stasis and thrombosis.

Following decannulation, patients should undergo routine duplex imaging for deep venous thrombosis assessment.

Limb ischemia also is a devastating complication that is not infrequent. The proximity of the femoral cannulas to the femoral nerve can lead to pressure ischemia on the femoral nerve and subsequent foot drop. Local wound infections and skin breakdown are common. Plastic surgery and wound care management are mandatory in any robust ECMO program that performs a large volume of cannulations.

Long-term physical therapy is mandatory after ECMO therapy, not only for the chronic effects of pulmonary scarring after severe ARDS, but also for the additional effects of ECMO cannulation.

Pre-cannulation history of peripheral vascular disease is considered a risk factor for post-ECMO limb ischemia.[161]

Most ICU patients are not routinely followed up in post-ICU clinics; however, the degree of limb, skin, wound, cardiopulmonary disability, and psychological setbacks from long-duration ECMO for ARF ideally should prompt consideration for following these patients in a post-ICU ECMO clinic.[162] These developments represent the next opportunity for maximizing care for patients treated with any mechanical circulatory support device in the ICU.

Deep Venous Thrombosis and Pulmonary Embolism

Due to the large cannula size required for stable ECMO flows, venous and arterial thrombosis can develop downstream to the access sites. Thrombosis is also associated with the prothrombotic state that occurs with ECMO.[149] On average, deep venous thromboses (DVTs) are found at a rate of 8.1 per 1000 cannula-days.[163] Cannula-associated DVT was identified in 18% of ECMO survivors, with dual-lumen jugular cannulation having a higher observed rate of thrombosis compared with single-lumen femoral cannulation.[163]

Menaker et al. assessed the prevalence of cannula associated DVT in 70 patients undergoing VV ECMO for severe ARDS; 85% of patients demonstrated venous thrombosis on routine ultrasound 24 h after decannulation.[164] A separate study that assessed the utility of CT scanning for DVTs after decannulation demonstrated that cannula-associated DVT was found in 75 of 105 patients (71.4%).[48] These investigators found that Fem–Fem cannulation induced cannula-associated DVT more frequently than Fem–IJ cannulation (69.2% vs. 63.1%), and that 17 of the 105 patients (16.2%) had a pulmonary embolism.[48] This finding is particularly important because patients who are cannulated for ARF already have compromised pulmonary function, and the pulmonary embolism burden further contributes to long-term chronic respiratory failure.

SPECIAL POPULATIONS

Three populations of patients undergoing treatment with ECMO warrant special consideration: those with SARS-CoV-19, those on hemodialysis, and patients being considered for lung transplantation.

SARS-CoV-19

Based on the favorable clinical outcomes of VV ECMO in the H1N1 pandemic, many clinicians and centers have used the same strategy in SARS-CoV-19–related ARDS. In contradistinction to H1N1, SARS-CoV-19 presented with several challenges, including system-wide capacity problems, population-level resource utilization, and manufacture/supply issues. ECMO is a scarce and time-consuming resource. Therefore, when hospital systems are overloaded, ECMO is not the most ideal treatment choice.

Patients with SARS-CoV-19 presented with both thrombotic and hemorrhagic complications in the lung, system vasculature, and brain,[163] leading to some reports of intracranial hemorrhage and thrombosis associated with ECMO.[165] Early reports suggested a 90% mortality rate for patients with SARS-CoV-19–related ARDS treated with ECMO,[166] prompting caution at several centers in employing VV ECMO in treatment of ARDS due to SARS-CoV-19. Eventually, the Extracorporeal Life Support Organization (ELSO) produced a data registry report of 1093 patients with ARDS due to SARS-CoV-19 who were treated with ECMO and had an average P/F ratio of 72. The median time from initiation of MV to VV ECMO support was 4 days; 94% of patients were cannulated to VV ECMO. Renal replacement was required in up to 44% of patients, which is higher than non–SARS-Cov-19 patients treated with ECMO.[167] CNS hemorrhage and thrombosis occurred 6% and 0.7% of patients, respectively; 57% of patients were discharged alive and 39% died.[167] The estimated cumulative mortality was 38% after initiation of VV ECMO for ARDS, consistent with results for non–SARS-Cov-19–related ARDS treated with ECMO.

As highlighted previously, in the EOLIA trial, the mortality rate for patients with ARDS managed with ECMO was 35%, while mortality for patients in the conventional arm (treated with MV) was 46%.[35] One of the challenges with SARS-CoV-19–related ARDS is that it does not fit the typical Berlin criteria for ARDS. Consequently, patients may present with hypoxemic respiratory failure and normal compliance. As noted during the H1N1 pandemic, several other registry and retrospective publications have corroborated evidence from the ELSO registry for use of VV ECMO in managing patients with SARS-CoV-19.[168] Average mortality is approximately 50% for severe SARS-CoV-19-related ARDS managed with VV ECMO. Therefore, use of VV ECMO in treatment of SARS-Cov-19, depending on the level of surge, hospital capacity, and resource availability, remains a good option in the armamentarium to manage ARF.

Dialysis and Renal Failure

As highlighted previously, fluid management and fluid balance are critically important in maintaining the ECMO circuit and optimizing lung function. Pulmonary edema and interstitial fluid accumulation hinder optimal lung ventilation and oxygenation. The inflammation associated with ARDS should be managed both with fluid restriction and diuretics.

Concurrent acute kidney injury commonly exists with ARF.[169] Renal replacement therapy is often necessary with ECMO. Performing CRRT during ECMO can be considered in three major configurations: (1) RRT through venous access independent of the ECMO circuit, (2) introduction of a hemofiltration filter into the ECMO circuit using intravenous infusion pumps to control the ultrafiltrate volume, and (3) inclusion of a CRRT device in the ECMO circuit.[170] Patients who require any type of ECMO and CRRT have an increased in-hospital mortality odds ratio of 6.5; however, patients with ECMO with CRRT have better fluid balance for the duration of the ECMO run.[170,171] Unfortunately, hemolysis increases exponentially with introduction of a second extracorporeal circuit.[172]

Pre–Lung Transplant

Lung transplantation is a curative treatment for end-stage lung disease. Allocation for lung transplantation is determined by the lung allocation score (LAS). The LAS prioritizes patients who are critically ill, and implementation of the LAS has led decreased wait times for those patients.[173]

Pretransplant mechanical ventilation is considered a risk factor for increased posttransplant mortality.[174] Due to the limited supply of donors and the large volume of patients on the transplant list, many patients die while awaiting transplantation.[173] VV ECMO can help bridge patients with complete lung failure to lung transplantation. A typical cannulation strategy includes awake, ambulatory IJ DLSC cannulation, as well as IJ–Fem cannulation. Challenges with awake cannulation include air embolism during cannulation and the inability of the patient to lie supine during vascular access. Technical expertise is required for awake IJ cannulation. Patients who are awake on VV ECMO can participate in physical therapy. However, challenges include refractory coughing, tracheostomy bleeding, changes in intrathoracic pressure, and volume shifts, which can result in suck-down and flow limitations. Blood transfusion should be limited in the pretransplant setting in order to avoid alloimmunization and crossmatching difficulties. Therefore, fluid management and blood administration remain challenges, and utmost care is needed for patients cannulated pretransplantation.

Future technologic advances that are currently in development include implantable lung assist devices, much like left ventricular assist devices, that can provide continuous support while patients await bridge to transplantation or bridge to destination.[175,176] These devices are implanted in the right chest after a right pneumonectomy of the diseased lung. Inflow is from a graft sewn to the right pulmonary artery, and outflow is from a graft sewn into the pulmonary vein. These devices are “pumpless,” utilizing the native RV cardiac function for forward flow.

Initially there was reluctance to use VV ECMO as bridge to transplantation. Data were limited, and one of the largest studies included only 17 VV ECMO cases in 1305 lung transplant patients. In this report, Bermudez et al. demonstrated that 30-day, 1-year, and 3-year mortality were 81%, 74%, and 65%, respectively, for VV ECMO support as a bridge to transplantation, versus 93%, 78%, and 62%, respectively, for patients on mechanical ventilation prior to transplant without ECMO support.[177]

As technology has improved, VV ECMO has become much more prevalent in patients awaiting lung transplantation. As of 2017, approximately 5% of lung transplants occur in patients receiving ambulatory VV ECMO or who are mechanically ventilated while on VV ECMO; the number has been rising exponentially.[155,178] With increased frequency of VV ECMO as a bridge to transplant, and in parallel with growing experience, mortality in the pre–lung transplant VV ECMO group has declined.[179]

Tipograf et al. analyzed 121 pre–lung transplant patients who were listed for transplantation on VV ECMO as a bridge to transplantation. Of these, 70 patients were successfully transplanted. Of the 70, 64 survived to hospital discharge, and 88% of those who survived to discharge were alive at 1 year; 83% were alive at 5 years.[180] Propensity matching between bridge-to-transplant versus non-bridge-to-transplant did not show a significant difference in survival, despite differences in lung allocation score.[180]

Avoidance of mechanical ventilation and use of awake VV ECMO is the preferred strategy for patients who require ECMO prior to transplantation. Such an approach is associated with a 30% survival benefit.[181] A retrospective analysis reported an 80% 6-month survival post-transplant for patients bridged with ECMO compared with a 50% survival for patients bridged with preoperative mechanical ventilation.[181]

EXTRACORPOREAL CARBON DIOXIDE REMOVAL

An extracorporeal membrane can be used for CO_2 removal, as well as oxygenation, as described briefly below.

Acute Respiratory Distress Syndrome with Hypercarbic Failure

The extracorporeal membrane is much more efficient at removing CO_2 than adding oxygen. CO_2 removal requires less blood flow through the circuit and membrane and is associated with fewer thrombotic and bleeding effects due to smaller cannula size, lower dose requirements for anticoagulation, and design as a dual-lumen, single-vessel access catheter.

After the initial unsuccessful trial for VA ECMO in ARDS, Gattinoni and Kolobow used low-flow $ECCO_2R$ to accomplish extremely low-tidal volume, low-stretch mechanical ventilation.[13,182,183] They hypothesized that they could divorce the ventilator oxygenation function from the ventilator CO_2 removal function. In order to accomplish this, an extracorporeal device was conceptualized that removed CO_2 and provided “lung rest” by limiting mechanical ventilation through decreased tidal volumes and decreased respiratory rates.[13] Oxygenation was envisioned as occurring with passive or ultralow-tidal-volume settings. The investigators published a trial of patients with ARDS who had isolated hypercarbic respiratory acidosis and were already being treated with tidal volumes of 6 mL/kg tidal.[117] Patients were cannulated with a 14F dual-lumen catheter. They were ventilated using a low-stretch/ultralow-tidal-volume ventilator setting, and $ECCO_2R$ with a hemofilter was implemented. A total of 32 patients were enrolled. Results demonstrated that the low-stretch protocol with $ECCO_2R$ hemolung reduced lung cytokine production in ARDS, suggesting less ventilator-induced lung injury.[184]

$ECCO_2R$ can be used as an adjunct to mechanical ventilation to reduce the level of support required of the ventilator and, potentially, to delay impending respiratory failure and need for intubation. Most patients with severe ARDS have hypercarbic, as well as hypoxic, respiratory failure; however, prior to severe ARDS disease progression, in patients with mild or moderate ARDS, $ECCO_2R$ can facilitate application of very low tidal volumes by correcting acidosis and hypercarbic failure while the ventilator is used for oxygenation. Investigators have demonstrated that this strategy can reduce inflammatory markers by using $ECCO_2R$-supported reductions in plateau pressures. However, one study failed to demonstrate a reduction in overall ventilator days.[117] Using a decision tree to appropriately select configuration strategy is useful.

Chronic Obstructive Pulmonary Disease

Acute-on-chronic respiratory failure, particularly that due to chronic obstructive pulmonary disease, represents the most common indication for $ECCO_2R$. Several case series have demonstrated use of $ECCO_2R$ to correct severe hypercarbic respiratory acidosis.[185–187] Other cases have demonstrated that $ECCO_2R$ may be used to avoid mechanical ventilation and intubation for acute exacerbations of chronic obstructive pulmonary disease exacerbations requiring noninvasive ventilation (e.g., using BiPAP).[188]

CHAPTER 150

Nutrition in Pulmonary Disease

Tachira Tavarez
David S. Seres

INTRODUCTION

The practice of clinical nutrition, particularly in the setting of acute illness, is somewhat complex due to the multiple interactions between disease and the ability to nourish patients. Much of clinical practice is based on observation or on flawed, biased, or severely underpowered studies. Furthermore, terminology related to malnutrition is extremely confusing: terms referring to problems attributable to alterations in nutritional intake are intermixed with those phenomena secondary to inflammatory illness, such as disease-related muscle wasting, which are not responsive to changes in nutrition intake.

Many excellent clinical publications[1,2] review general and specific nutritional concepts. This chapter introduces newly adopted definitions for malnutrition and their clinical utility, and reviews approaches to the clinical challenges specific to selected pulmonary diseases, acute respiratory failure, and the critical care setting. Chronic obstructive pulmonary disease (COPD) and cystic fibrosis (CF) serve as the prototypes for nutrition-related issues encountered in chronic pulmonary disease.

MALNUTRITION REDEFINED

Malnutrition has long been known to be associated with poor outcomes in medical and surgical patients.[3] However, for decades, the terminology describing malnutrition has created great confusion, incorporating biomarkers, such as albumin, which have since been disproven as reflective of dietary intake. While new efforts focus on defining malnutrition based on etiology,[4] the use of clinical parameters unrelated and unresponsive to nutrient intake[5] remain entrenched. The new definition of malnutrition (Table 150-1), adopted by major nutrition organizations in the United States, describes two forms: malnutrition due to nutrient imbalance or malnourishment (e.g., starvation, marasmus, obesity), and that which occurs due to systemic illness (e.g., catabolism, cachexia).[6] Only malnutrition due to nutrient imbalance resulting from alterations in intake or uptake can be treated by alterations in nourishment. It remains challenging, however, to decipher whether alterations in body habitus are due to illness, or due to altered intake, or both, and even whether and when changes in intake or nutrient levels represent deficiency or disease epiphenomena. While the new definitions have not been validated to predict which patients will respond to nutritional interventions, they are highly predictive of overall outcomes.[7]

TABLE 150-1 Findings in the New Definition of Malnutrition

	Starvation-related Malnutrition (Malnourishment)	Disease-related Malnutrition
Starvation	X	X
Fat wasting	X	+/−
Muscle wasting	X	X
Hypoproteinemia		X
Elevated inflammatory markers		X

Inflammatory markers, such as C-reactive protein, and serum albumin and prealbumin, do not correlate with nutrient intake, and the belief that most traditional markers of malnutrition (e.g., albumin, prealbumin [transthyretin], measures of immune function) reflect adequacy of nourishment has been disproved.[5] Despite this, not all of these markers have been removed from the new definition.[4] While it still may be surprising to many clinicians that many so-called nutritional markers are, in truth, markers of systemic inflammation, this is far from a new finding.[8,9] Discussion of alterations in serum albumin and other parameters as arising from systemic inflammation has appeared in physiology and biology texts for decades.[10] However, these "nutritional" markers have long been known to identify patients at high risk for untoward outcomes and to reflect severity of illness.[9] Moreover, nutritional assessments that incorporate the markers, such as the Prognostic Inflammatory and Nutritional Index (PINI),[11] are highly validated to predict poor outcomes. Importantly, recent research has shown that the level of systemic inflammatory response (e.g., elevated CRP) is predictive of response to nutritional interventions.[12]

Confusion surrounding how to define malnutrition will likely continue because clinical findings, which may be caused by starvation, systemic inflammation, or both, remain as diagnostic criteria. The etiology of these signs may be difficult, if not impossible, to distinguish clinically. Lean body mass loss due to inflammation, for example, does not respond to stand-alone nourishment strategies when inflammation is present. In other words, patients diagnosed with "malnutrition" may or may not actually be "malnourished." Well-nourished patients (e.g., those receiving tube feeding or eating well) with disease-related muscle wasting are "cachectic," but not malnourished. Weight maintenance or gain, especially related to maintenance or increase in lean mass, is considered desirable because of the association between low weight and morbidity and mortality.[13] However, weight loss is not, by itself, an adverse outcome due to poor nourishment in sick patients. Rather, it is more likely an epiphenomenon and a marker of disease severity.

For example, until systemic inflammation is resolved, serum albumin levels and muscle mass will not normalize, despite protein supplementation. Conversely, normalization of serum albumin may occur despite starvation, once systemic inflammation has resolved.[14] Prealbumin, properly referred to as transthyretin, normalizes more quickly than albumin with resolution of systemic inflammation, but it is no more reflective of adequacy of nutritional intake than is albumin. Moreover, nutritional supplementation has not proved to slow the decrements seen in these markers.

Traditional nutritional markers, such as serum proteins and muscle mass, should be considered surrogates for systemic inflammation and not markers for adequacy of nourishment. Nor should they be seen as an indication for nutrition support. For example, administration of parenteral nutrition in response to finding a low serum albumin in a patient who is eating and absorbing nutrients normally exposes the patient to potential harm without potential benefit.

Defining ideal nourishment for an individual patient is extraordinarily difficult due to a lack of granular clinical research. Moreover, much nutrition research reports impact on surrogate markers, such as lean mass, immunologic and inflammatory makers, and serum proteins, rather than appropriate clinical outcomes. Meaningful outcomes resulting from nutrition support include a reduction in morbidity, cost of care, and mortality.[15] These, however, require larger, costlier, and more complex randomized trials than are often performed.

Given the complexity of malnutrition, the work of nutrition practitioners conducting clinical assessments is particularly important in identifying high-risk patients. Insurers have recognized that patients with "malnutrition" are more complex than those who are not and have increased their reimbursement to hospitals for these patients. The authors contend that dietitians should be renamed "riskologists" to acknowledge this added value, and that patients identified as "at risk for nutritional complications" be relabeled "very sick and at risk for morbidity and mortality." In addition, patients so identified should receive intensive oversight by a multidisciplinary team of highly qualified clinicians.

TERMINOLOGY

The two previously noted forms of malnutrition often coexist. Sick patients often exhibit anorexia and decreased nutritional intake. In this instance, loss of muscle mass is due to both systemic inflammation and lack of nutritional intake. Distinguishing between the two forms is difficult. Recognizing a component of caloric deficit provides an opportunity to intervene.

In distinguishing between the two types of malnutrition, the terminology employed should be very specific.[4] As mentioned, patients with *disease-related malnutrition* who are well fed are not *malnourished*. Undernourishment, starvation, nutritional deficiency, nutritional imbalance, obesity, and nutritional excess are terms that may be used to describe imbalance-related malnutrition. Conversely, catabolism and disease-related malnutrition are used synonymously with malnutrition due to inflammation. *Marasmus* is an older term that refers to pure starvation. *Kwashiorkor*, an endemic disease in children, is likely due to systemic inflammatory response, but the term is no longer applied to hospitalized patients, especially adults, in nonendemic areas.[16] *Cachexia* is the syndrome resulting from severe chronic malnutrition, which contains a component of inflammation-related malnutrition.[17] It results, at least in part, from catabolism. Cachexia may be predominantly due to inflammation, with a smaller component of starvation, or alternatively, from starvation with a smaller component of inflammation.

ETIOLOGY AND MECHANISMS

Imbalance-related malnutrition is a result of inadequate nutrition, and it is treatable by feeding or supplementation. On the other hand, disease-related malnutrition is neither due to, nor responsive to, changes in calorie or protein intake.[15] The mechanism for inflammation-related muscle wasting that occurs despite adequate or supplemental nutrition is poorly understood, but it is clearly related to production of inflammatory cytokines.[18] One proposed mechanism is that muscle breakdown supports uncontrolled hepatic gluconeogenesis resulting from the insulin resistance observed in this setting. The decrement in serum albumin, as well as in other carrier proteins, is likely due to its extravasation from capillaries, along with other macromolecules, due to increases in capillary permeability arising with inflammation. With maintenance of vascular volume, plasma protein concentrations are diluted. In addition, plasma protein oncotic pressure falls, or becomes nonexistent, and plays a diminished role in minimizing fluid flux across capillary membranes into soft tissues, once normally semipermeable capillary membranes become permeable.

UTILITY

Diagnosing malnutrition certainly identifies patients at highest risk for poor outcomes,[7] and nutritional assessment will identify patients with, or at risk for, poor intake for whom nutritional interventions may be necessary. Understanding the etiology of malnutrition in the individual patient determines the utility of nutritional assessment. Recognizing ongoing inflammation by "nutritional" assessment may lead to recognition of a medical or surgical condition that may require medical or surgical, rather than nutritional, intervention or help to guide ethical decision-making. Prolonged, untreatable catabolism may predict incurable or fatal illness, and inflammatory markers have been shown to predict whether nutrition interventions will have benefit.[12] Low muscle mass may be hidden in an obese patient with preserved adiposity, but it can be discerned with careful physical examination and may help explain a delay in physical recovery. Muscle mass is an important determinate of serum creatinine concentrations. Physical assessment of muscle mass may also be important in explaining whether a widening of the ratio of blood urea nitrogen (BUN) to creatinine represents hypoperfusion or hypovolemia on the one hand, or severe muscle loss with renal impairment on the other.

Albumin levels require approximately 6 weeks to normalize once inflammation resolves. Consequently, direct markers of inflammation (e.g., C-reactive protein and cytokines) may provide a more accurate measure of inflammation in the presence of persistent hypoalbuminemia. Reversal of hypoalbuminemia is a helpful sign in tracking resolution of inflammation and may indicate a better prognosis; however, trending in albumin levels over weeks is required for the measurements to be useful in this regard.

Consequently, the work of nutrition practitioners conducting clinical assessments is very important and adds value by identifying patients at high risk for overall poor outcomes and complications, irrespective of whether a nutritional intervention is indicated. Patients so identified should receive intensive oversight by a multidisciplinary team of highly qualified clinicians. Further, insurers have recognized that patients with "malnutrition" are more complex than those without and accept malnutrition as a comorbid condition to adjust reimbursement to hospitals.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is an extremely common form of chronic lung disease. Nutritional management of patients with COPD may be challenging and frequently entails consideration of both starvation and disease-related malnutrition.

■ Malnutrition in COPD

COPD encompasses several systemic manifestations, including malnutrition, and should, therefore, not be considered solely a pulmonary disease. Muscle dysfunction and wasting are both common manifestations, and cachexia is common in COPD. Muscle wasting is reflected by a decrease in fat-free mass, which is a known predictor of mortality in patients with COPD.[19]

The underlying mechanisms of muscle wasting and dysfunction are complex and difficult to ascertain from existing epidemiologic and observational studies. Evidence suggests cachexia in COPD is partly related to systemic inflammation and increased oxidative stress.[20–22] It has long been known that weight loss in COPD is associated with an increase in inflammatory markers such as TNF-α.[23]

Given the systemic nature of cachexia and muscle dysfunction in COPD, purely nutritional strategies would be expected to have little impact on outcomes. Notably, and as discussed previously, weight gain is solely a surrogate marker and not a meaningful clinical outcome. While weight gain may be desirable, it may not be associated with improvement in quality or quantity of life or a decrease in the cost of care. In fact, until recently, whether nutrition support had any clinical outcome benefits was unclear, even though patients given such support gained weight.[17] Recent studies, which reassessed data in patients with COPD who received nutrition support compared with those who did not, demonstrated weight gain in the treated group, as well as improvements in both skeletal and pulmonary muscle function and fat mass. In addition, improvement in health-related quality of life (HRQOL) was observed when data using the St. George's Respiratory Questionnaire (SGRQ) were analyzed, although not when data from SGRQ were pooled with data from the Chronic Respiratory Questionnaire (CRQ).[18] Although this is low-quality evidence, it is reasonable to continue to recommend that patients with COPD who are undernourished receive nutrition support. That said, failure to gain weight, or to stem weight loss, should be contextualized in terms of disease process rather than patient adherence.

Macronutrients in COPD

A great deal of attention has been paid to concerns about the impact of macronutrients in COPD. Because carbohydrates are metabolized to CO_2 and water, concern exists that a diet or tube feeding high in carbohydrate content may result in increases in work of respiration or Pa_{CO_2} and, consequently, adverse outcomes. While initial studies seemed to support this concern, recent investigations suggest the opposite. In one study, nutritional supplementation using a high-fat product resulted in more dyspnea with exercise than did a high-carbohydrate product.[24] While the respiratory quotient (RQ)—the ratio of carbon dioxide produced to oxygen consumed per minute ($\dot{V}_{CO_2}/\dot{V}_{O_2}$)—increases more with a high-carbohydrate supplement, oxygen consumption is lower than that seen using a high-fat supplement.

While these findings are counterintuitive, they are consistent with studies of skeletal muscle in patients with COPD, which suggest impaired fat metabolism and an increase in carbohydrate metabolism. In these patients, studies have shown a decrease in oxidative function[25] and expression of peroxisome proliferator-activated receptors (PPAR),[26] which have an extremely important role in upregulating lipid uptake and metabolism in cells. In addition, in COPD, a shift from oxidative to glycolytic muscle fibers occurs in skeletal muscle, the degree to which is directly correlated with disease severity.[23] In theory, fat causes a delay of gastric emptying, so a full stomach may be responsible for the increase in dyspnea.

Amino acids, specifically branched amino acids (BCAAs), serve as alternate sources of fuel via their conversion into glutamine in muscle.[27] Serum BCAAs are low in patients with COPD compared with matched controls, and more so in underweight patients with COPD.[28] These serum levels were shown to correlate with anthropometric measures like ideal body weight and percentage arm muscle circumference. In one study, plasma concentrations of BCAAs correlated with muscle energy metabolism in patients with COPD, indicating that low BCAA levels are associated with alterations in muscle energy metabolism in these patients.[29] The hypothesis is that supplementation with BCAAs should improve exercise capacity. There have only been small studies involving BCAA and protein supplementation,[30,31] and there are currently no specific guidelines BCAA supplementation.[32]

Macronutrient mix in COPD may be far less important than previously thought, but total calories may play an important role. In a nutritional supplementation study, provision of excess calories to subjects with COPD was shown to cause a decrease in exercise performance. This was most profound in patients with more advanced disease and cachexia.[33]

Other Nutrition-related Considerations in COPD

Anabolic steroids have been demonstrated to increase fat-free mass in patients with COPD but have been proven to have minimal benefit in clinical outcomes. In a study of patients with COPD enrolled in a pulmonary rehabilitation program, those who received an anabolic steroid had a higher fat-free mass than those who did not, but improvements in muscle function, exercise capacity, and health status were not different between the two groups. Patients who received corticosteroids demonstrated less response to the rehabilitation. Maximal inspiratory mouth pressure and peak workload were improved in patients receiving both chronic corticosteroids and anabolic steroids compared with those given placebo; this was the only positive outcome.[34]

Appetite stimulants have not proved effective in improving outcomes in COPD. In a study of patients receiving megestrol acetate versus those receiving placebo, the treated group demonstrated a lower 6-min walk distance, despite having a decreased Pa_{CO_2} and increased Pa_{O_2}. Megestrol increased weight, but it did so by increasing fat mass.[35] No studies on use of cannabinoid appetite stimulants in COPD are available.

Recommendations

Patients with COPD should be screened for malnutrition and referred to a nutrition practitioner when any sign of diminished nutritional intake or weight loss is found. Similarly, obesity or excess weight gain in an individual previously of normal weight should serve as indications for nutritional intervention.

The authors' opinion is that as an initial goal, it is reasonable to choose a nutritional prescription based on either an estimate of basal requirements at ideal weight, or calorimetric measurement of basal metabolic rate, and increases aimed at slow (1–2 lb per week or 3600–7200 kcal excess per week) weight gain. Consultation with a nutrition clinician is recommended, and care should be taken to avoid overfeeding.

Because of difficulties in distinguishing malnourishment from disease-related changes, along with the inability of nutrition support to impact the latter, failure of nutritional interventions should be viewed as evidence of disease progression and factored into prognostic assessments. Strategies such as appetite stimulation and use of anabolic steroids may impact selected metrics, but they have not been demonstrated to impact outcomes. Measuring and monitoring markers, such as serum albumin, should be considered, but the results should be viewed as reflective of an underlying inflammatory state. In this regard, they may be prognostic but not reflective of nutritional adequacy.[14,15]

CYSTIC FIBROSIS

Cystic fibrosis (CF) is associated with nutritional issues that are far more complex than in most other pulmonary diseases. Patients with CF are prone to significant chronic inflammation, with acute worsening in the presence of infection. As in other inflammatory disorders, disease-related muscle wasting may be noted, and although not necessarily obvious, it may be evident even at an early age.[36]

Patients with CF are at high risk for malnutrition arising from a both systemic and local, gastrointestinal (GI) impairments. There is inflammation-mediated anorexia, increased energy expenditure, and essential fatty acid turnover. GI issues include malabsorption due to exocrine pancreatic insufficiency, dysphagia due to gastroesophageal reflux disease, issues with motility due to both delayed gastric emptying and small bowel transit time, and CF-related liver disease.[37]

Macronutrients and Micronutrients in Cystic Fibrosis

No properly designed, prospective, randomized controlled trials comparing enteral feeding to no intervention have been conducted in CF to determine whether enteral feeding improves outcomes.[38] Such studies are nearly impossible to perform because of the ethical dilemmas posed by not providing supplemental or artificial feeding to patients who are, as best as we can determine, chronically starved.

Regarding the macronutrients, a current pediatric consensus statement emphasizes the importance of a higher proportion of dietary fat intake compared to that of the general population.[39] According to the recommendation, dietary fat should compose 35% to 40% of total caloric intake. A high-fat diet has been implemented for patients with CF since a study in the 1980s comparing a cohort of CF patients in Toronto with a similar cohort in Boston suggested improved survival due to a higher-fat diet.[40] Supplementation with fatty acids, such as omega-3 fatty acids, also has been considered, given the evidence of fatty acid malabsorption and inflammation-induced increased catabolism in patients with CF.[37] However, evidence for the use of omega-3 fatty acids is limited to small studies that only suggest a possible benefit.[41]

Various vitamins and minerals have been considered in CF. CF patients with pancreatic insufficiency are particularly at risk for deficiencies in fat-soluble vitamins A, D, E, and K. Supplementation is recommended in most current adult and pediatric consensus statements[39,42] despite low-quality evidence.[43,44] Among the minerals considered in CF—a disorder characterized by immune dysfunction—zinc has long been of interest. Zinc deficiency may cause untoward immunologic changes, but zinc supplementation in the setting of normal levels generally has no beneficial effect and may be harmful. Zinc supplementation lowers copper levels,[45] and copper deficiency caused by excessive zinc ingestion may result in mortality.[46,47] Only a few trials, with small number of subjects, have assessed the efficacy of wholesale zinc supplementation for CF. Not surprisingly, zinc supplementation in patients with CF who have normal zinc levels has demonstrated no significant benefit, while supplementation in those with low zinc levels results in fewer days on antibiotics.[48]

■ Feeding and Pancreatic Insufficiency

Multiple approaches have been employed to overcome the complex feeding issues encountered in CF, including use of special, predigested tube feeding mixes and supplementation of nutrients thought to be supportive of immune function. Given difficulties with maldigestion due to pancreatic insufficiency and resulting malabsorption in patients with CF, the concept has arisen that providing partially predigested feedings may enhance absorption. However, in small studies, provision of predigested feedings appears not to improve absorption over use of enzyme replacement therapy.[49] Our approach is to feed patients concentrated, high-fat tube-feed products, enabling provision of goal calories in the face of small bowel dysmotility.

In recent years, the production of powdered pancreatic enzyme replacements has ceased. Currently, the primary form of pancreatic enzyme replacement is an enteric-coated product. Administration of the product through a gastric tube requires that the outer capsule be opened, exposing coated spherules that require suspension prior to administration. However, the spherules tend to coalesce and may clog the tube. One proposed method to avoid this problem is to mix the spherules into a viscous solution prior to administration,[35] thereby keeping them suspended and preventing settling and coalescence. Others recommend dissolution of the spherules in an alkaline solution, which is then added to the feed product and allowed to sit prior to administration, resulting in feed predigestion. While addition of enzymes to the feed may facilitate predigestion, concern exists that any manipulation of feed products prior to feeding tube installation may increase the risk of bacterial contamination.[50] The data supporting this concern, however, relate primarily to bacterial counts, rather than clinical outcomes. However, an inline device that contains lipase was developed for CF patients who receive tube-feeds. This device was shown to increase the absorption of fatty acids and was also deemed safe and well tolerated.[51] Other small retrospective studies providing evidence of its ability support weight gain were presented in a recent editorial by several physicians and dieticians who work with patients with CF.[52]

■ Strategies and Recommendations

In an effort to improve patient education and clinical outcomes, multidisciplinary care, including early involvement by nutrition practitioners, is recommended for all patients with CF.[39,42] Nutrition practitioners should have specialized knowledge of CF, as the feeding and nutritional problems can be quite complex. Malabsorption may be particularly challenging when patients require tube feeding, especially jejunal tube feeding.

ACUTE RESPIRATORY FAILURE

The importance of adequate nutrition in patients with acute respiratory failure who are admitted to critical care units has been recognized for some time. Several practical considerations in administration of nutrition in this setting are outlined subsequently.

■ Specific Nutrients

Much has been written about the role of specific macro- and micronutrients in patients with acute respiratory failure. As discussed previously, attempts at manipulating the composition of the feedings administered—for example, the ratio of carbohydrate to fat—have been shown to be without benefit. Use of specific fats, especially oils containing omega-3 fats or their precursors, has been studied in the acute respiratory distress syndrome (ARDS), but the results are still debated.

Ten prospective clinical trials implementing omega-3 fatty acid based formulas or supplements were included in a recent Cochrane systematic review of immunonutrition.[53] In this review, 4 of the 10 studies used similar enteral formulas and high-fat, low carbohydrate, feeding strategies.[54–57] These four studies found that the use of the omega-3 formula resulted in decreases in the development of new organ failure, time on mechanical ventilation, and time in the ICU. However, results from the Cochrane systematic review found insufficient evidence for these outcomes, largely due to the heterogeneity between studies.

■ Timing and Route of Administration of Artificial Nutrition

The timing of initiation of enteral or parenteral feeding in critically ill patients appears to be clinically important.[58] Early enteral feeding has become standard of care in the critically ill.[59] However, studies of this practice have limitations and risks for bias.[60,61] While early enteral feeding does not stand up to the strictest requirements for evidence-based practice and garners a low grade in evidence-based guidelines,[59] a large body of evidence indicates that food in the gut may play an important role in modulating systemic inflammatory response,[62] which theoretically may lead to preservation of immune function, less catabolism, and fewer complications. Indeed, in many cases the physiologic basis for septic shock may be related to interactions between gut pathogens and mucosal cells, with or without actual septicemia.[62]

Enteral nutrition (Tables 150-2 to 150-4), except in the face of severe prolonged gut failure, is almost always preferred over parenteral nutrition.[59] Early parenteral nutrition, whether the sole source of calories,[63] or as a means of augmenting enteral nutrition,[64] has not proved beneficial in critically ill patients and may, in fact, be harmful (Table 150-5). The time point at which the risks of starvation exceed the risks of parenteral nutrition is unknown, since most studies have excluded patients already suffering from malnutrition.[48] American guidelines recommend withholding parenteral nutrition during the first week of critical illness when enteral feeding is not possible.[59] Multiple randomized trials showed an increase in *morbidity* when parenteral nutrition was added to early enteral feeding, including a large trial with more than 2000 subjects.[64,65]

TABLE 150-2 Choice of Route for Administration of Enteral Nutrition

Large-bore nasogastric sump tube
Short-term (several days) feeding
Transition from gastric drainage to gastric feeding
Small-bore nasogastric feeding tube
Primary choice for nasal tubes
Short-term (up to 30–90 d)
Small-bore nasoenteric (nasoduodenal, nasojejunal)[a]
Gastric dysmotility[b]
Very high aspiration risk[c]
Gastrostomy (percutaneous endoscopic, surgical)
Long-term (>30–90 d)
Technical issues with nasal tube[d]
Jejunostomy (percutaneous endoscopic, surgical)
Gastric dysfunction[a]
Long-term access when gastric surgery anticipated[e]
Long-term access when gastric tube not possible[e]

[a] *Usually 6–10 French in adults.*

[b] *Concomitant gastric drainage is likely to be required or vomiting can occur. Short term, a second (nasogastric sump) draining tube or use of a combined dual-lumen nasogastrojejunal (draining nasogastric, feeding nasojejunal) tube may be useful. Combined dual-tube draining gastrostomy–feeding jejunostomy may be useful longer term.*

[c] *This recommendation appears in guidelines but is not supported by prospective randomized data. While jejunal placement may result in better calorie delivery, there are no outcome data to support routine choice of jejunal, over gastric, placement of feeding tubes.*

[d] *With the availability of techniques, such as the nasal bridle for securing nasal tubes, security of the tube is less commonly an indication for percutaneous feeding tubes.*

[e] *For example, patients with gastric cancer, or esophageal cancer and planned esophagectomy and gastric pull-up.*

■ Total Calories Provided

Whether critically ill patients should receive 100% of estimated or measured calorie needs, especially early in the course of their critical illness, is the subject of great debate. Failure of current practice to deliver "adequate" calories to critically ill patients has also received a great deal of attention. A recent study suggests that patients admitted to ICUs receive only about 35% of prescribed calories and 42% of their prescribed protein requirements during the first few days of their stay.[66] As a consequence, significant efforts have been made to increase calorie delivery through protocol development and quality improvement initiatives,[67] as well as through immediate initiation of parenteral nutrition to "top off" the calories that early enteral nutrition cannot provide.[68] However, the outcome benefits of these approaches have not been proven.

In the absence of high-quality, prospective, randomized studies, we do not know how to determine the individual caloric needs of critically ill patients. Indirect calorimetry has the potential to lead us completely astray. No currently available marker, assessment tool, or nutritional score can help discern what calorie and protein prescriptions will result in the best clinical outcomes.[5] In addition, high-quality studies in which calorie top-off was achieved enterally[69] or parenterally[64] have showed no benefit. Moreover, complications such as gastrointestinal intolerance with full enteral feeding[69,70] and prolonged length of stay may occur with a parenteral top-off approach.[64] The findings from the studies using parenteral nutrition have been criticized by proponents of early achievement of calorie goals on the basis that the investigators used a parenteral nutrition practice different from that employed in North America; in fact, two small studies suggest a benefit.[68,71] However, these smaller studies have significant limitations, and given the rigor of the larger parenteral study, its findings cannot be dismissed.

■ Position and Timing of Feeding Tube Placement

The choice of enteral feeding tube location has been a focus of discussion in the critical care setting: gastric versus duodenal or jejunal. A related center of debate is the incidence of pneumonia with each choice. Overall, studies have shown an increase in calorie delivery using nasoenteric tubes compared with nasogastric tubes.[72] However, current investigations using more stringent feeding protocols do not demonstrate a benefit with nasoenteric tube placement, and neither mortality nor the incidence of pneumonia is affected by tube placement.[72,73]

In the setting of pancreatitis, when artificial feeding is needed, enteral feeding is the standard of care.[74] One would expect in the setting of severe pancreatitis that postpyloric tube placement is advantageous over gastric placement. However, whether the tube should be placed in the stomach or jejunum is still a subject of debate; comparative studies have failed to show any differences in outcomes between these methods.[75]

In recent times, the practice of simultaneous insertion of tracheostomy and PEG tubes (PEG-TRACH) has gained some traction.[59] In certain institutions, interventional pulmonologists or surgeons perform both procedures in the same setting, alone or in collaboration with a gastroenterologist. Tracheostomy is an important and beneficial adjunct in the management of the critically ill (Chapter 145). It is used when clinicians predict that a patient will need a prolonged period of mechanical ventilation. The procedure is well tolerated and may be performed at the bedside. Tracheostomy insertion has been associated with a faster wean from mechanical ventilation, reduced incidence of pneumonia, and, ultimately, shorter hospital stay.[60] Timing of tracheostomy insertion has been debated; a move toward earlier performance has been observed because of a suggestion of improved outcomes reported in meta-analysis.[61] However, recent trials have suggested lack of real benefit from early tracheostomy. Consequently, this practice is liable to change.[62,63] Nevertheless, at present, the combination procedure of PEG-TRACH has been advocated by some and has resulted in simultaneous, early PEG insertions (in some cases within 4 days of admission to ICU).[59] Historic observational data on the feasibility of this approach are available, although the effectiveness and safety of this approach have not been studied.[64,65]

We postulate, based on discussions with critical care colleagues throughout the country, that a large portion of the drive for simultaneous PEG-TRACH is based on refusal by nursing homes in some parts of the United States to accept patients with nasal feeding tubes, coupled with the push for shorter lengths of stay. In a phone survey of the 127 nursing homes (participation rate, 85%) in New York City, 88 (81.5% of respondents) indicated that they have policies prohibiting nasal feeding tubes. Twenty nursing homes (18.5% of respondents) indicated they would accept nasal tubes, but most had not in the past 6 to 12 months.

Gastroenterologists and interventional radiologists at our institution have estimated that a large percentage of the gastrostomies placed were done solely because of anticipated discharge of the patient to a nursing home. Most nursing homes reported that their refusal of nasal feeding tubes is based on the perception of high risk of aspiration and tube dislodgement.[66] This concern is unsubstantiated in the literature. Indeed, only a total of 686 patients have

TABLE 150-3 Usual Characteristics and Indications for Enteral Feeding Formulas

	Standard	Standard Concentrated	Standard High Protein	Renal	Diabetic	Predigested[a]	Pulmonary[b]	Immune/ Inflammation Modulating

Osmolarity[k]	Iso	Up to ∼700 mOsm/L	Iso or slightly increased	∼700 mOsm/L	Iso or slightly increased	Iso up to ∼700 mOsm/L	Increased	Iso or slightly increased

[a] *Predigested feeding products may be made up of simple sugars and individual amino acids (e.g., Vivonex) or of oligosaccharides and oligopeptides (e.g., Vital, Peptamen). These are marketed as providing superior tolerance and better absorption in states such as maldigestion and hypoproteinemia. Most of the data on these are preclinical, and there are no outcome data supporting their superiority. Very low-fat feeding has been promoted as an alternative to parenteral nutrition in patients with chyle leakage. Randomized studies are lacking.*

[b] *These products have not been shown to have any benefit in randomized trials. The principle on which they were created is that dietary fat produces less CO_2 than does carbohydrate. While this effect can be measured on calorimetry, patients are not extubated sooner. Certainly, these products are not indicated for patients on long-term ventilatory support.*

[c] *Most patients can be fed with a standard feeding product. The cost differential between a standard product and the disease-specific feeds can be as much as 15-fold.*

[d] *An increase in calorie density, from 1.0 to 1.5 kcal/mL, will not substantially increase viscosity and decreases the volume of tube feeding product required to meet calorie goals. The remainder of the volume requirements may be given as water boluses. This decreases overall feeding time and increases convenience for ambulatory patients.*

[e] *Patients with renal insufficiency and/or on hemodialysis, but not continuous renal replacement, require restriction of dietary sodium, potassium, and phosphorus. In addition, these products are fluid restricted.*

[f] *Glycemic index is the area under the curve of the rise in blood glucose after a bolus or meal, compared with a standard. This concept does not apply to patients receiving continuous feeding, as rate of appearance of glucose will be equal to rate of delivery plus rate of gluconeogenesis in these patients. Glycemic control formulas improve glycemic control only in patients fed intermittently.*

[g] *Because of the biochemical derangements that occur in critical illness, nutrient levels and consumption are altered. These alterations have led to a great interest in supplementation of specific nutrients to reverse these derangements. There is no strong evidence that these approaches result in improved outcomes. The author believes this may be due to these derangements being adaptive, or epiphenomena.*

[h] *Insoluble fiber, while favored in long-term tube feeding, should be avoided in critically ill patients, especially while on pressor agents. Bezoar may form when peristalsis is diminished.*

[i] *Fat content in these products varies. In some, it is highly restricted to 10% of calories (long-chain fat, Vivonex). In others, fat has been engineered to provide theoretical improvements in absorption and may contain mixtures of medium-chain, long-chain omega-3, and long-chain omega-6 fats.*

[j] *Fat content in these products varies widely. Products focused on inflammation may have a large amount of omega-3 and other putatively anti-inflammatory fats. Other products provide engineered triglycerides, with a mixture of long-chain omega-3 and omega-6 plus medium-chain fats. Discussed more fully in Acute Respiratory Failure/ Specific Nutrients section in text.*

[k] *Osmolarity of tube feeds ranges from isotonic to approximately two times isotonic. The osmolarity of many medications and electrolytes is orders of magnitude higher. The latter is a far more important concern when evaluation patients with diarrhea. It is unlikely the osmolarity of current tube feeding products will be the cause.*

been randomized in 9 trials comparing nasogastric feeding tube to PEG. PEG has been associated with fewer episodes of feeding interruption, tube blockage, tube leakage, or lack of adherence to treatment in a subset of 7 of these studies, which included only 314 patients. In aggregate, no differences were observed in the incidence of pneumonia or complication rates between the two feeding methods.[67]

Consensus guidelines suggest that PEG should be considered for patients likely to require enteral nutrition >30 days.[68] New York State Department of Health policy allows for nasal feeding tubes for up to 96 days[69] before considering PEG, but not placement, is required. PEG, while safe and reasonably well tolerated, is not a frivolous procedure. Mortality post–PEG insertion has been reported to be 26% at 30 days,[70] and as high as 43% at *1 week*.[71] These high rates are likely largely driven by poor patient selection. Based on these data, selection of critically ill patients undergoing tracheostomy for concurrent PEG insertion needs to be questioned. By virtue of their complex critical illness, patients undergoing tracheostomy are not at low risk for the procedure. The 30-day mortality post-tracheostomy has been variously reported at approximately 30%.[60,62] By extension, one may conclude that selection criteria for combined PEG-TRACH in these series resulted in an excess PEG insertion rate of at least 30%, without demonstrable outcome benefit.

In one series of patients undergoing simultaneous PEG-TRACH, the mortality at 30 days was 11%.[59] In the surviving patients, PEG tubes were removed in 73%, with a median of 76 days (range, 24–611 days). Thus, it seems likely that PEG insertion may have been avoided in many of these patients by deferring simultaneous insertion until the prognosis for resumption of oral diet and prognosis overall were clearer and the patient more medically stable.

In summary, nasogastric feeding tubes are widely regarded as safe and are the preferred option for short-term (30–90 days) delivery of nutrition. While the risks of simultaneous PEG-TRACH insertion appear to be tolerable, based mostly on anecdotal evidence, the procedure has not been proven to be superior to a “watch and wait” approach of continuing with nasogastric feeding. Patients undergoing simultaneous PEG-TRACH should be carefully chosen for procedural risk and likelihood of long-term requirement for a tube feeding.

TABLE 150-4 Challenges and Complications of Enteral Nourishment[a]

- Gastrointestinal intolerance
  - Abdominal distension
  - Nausea and vomiting
  - Diarrhea
    - Maldigestion/malabsorption
    - Contamination of enteral feeding solution
    - Infusion of hypertonic medications and solutions
    - Medication side effects
    - Gastrointestinal diseases
- Constipation
- Intestinal ischemia
- Gastroparesis and ileus
- Metabolic derangements
  - Hyperglycemia
  - Refeeding syndrome
    - Hypokalemia
    - Hypophosphatemia
    - Hypomagnesemia
    - Wernicke encephalopathy
- Dehydration
- Complications of tube access

[a] *Note that while aspiration and pneumonia are associated with use of enteral nutrition, recent studies have demonstrated a lack of relationship between even vomiting and pneumonia in patients receiving enteral nutrition.[76] Furthermore, the incidence of pneumonia does not appear to be decreased by positioning tubes in the jejunum.[57]*

TABLE 150-5 Complications of Parenteral Nutrition

- Complications of access
  - Bleeding
  - Infections
  - Venous thrombosis
- Metabolic complications
  - Refeeding syndrome
  - Hyperglycemia
  - Vitamin and mineral deficiencies due to shortages
- Systemic complications
  - Bacteremia/central line–associated blood stream infections (CLABSI)
  - Overall increased incidence of infections
  - Hepatic dysfunction
  - Prolonged ICU and hospital stays

■ Aspiration and Gastric Residual Volumes

Aspiration of gastric contents is a serious concern in the critically ill. But aspiration, by itself, should not be considered an adverse outcome unless it leads to a clinically significant event, such as ventilator-associated pneumonia. Aspiration is common in a variety of settings, such as intubation for routine surgery[72] and during sleep.[73,74] In a study published more than 40 years ago, aspiration was demonstrated in 50% of normal volunteers and in 75% of subjects with depressed consciousness.[74]

Based on the belief that the risk of aspiration is related to the volume of gastric contents, measurement of gastric residual volumes has become common practice in patients receiving enteral feeding. Many protocols and guidelines have been developed for managing tube feedings based on gastric residual volumes. Increasingly, however, this practice has been challenged. High gastric residual volumes are not associated with increases in ventilator-associated pneumonia. In fact, recent studies have questioned the value of checking gastric residuals at all. In a before–after study[75] and in a prospective randomized study,[76] checking gastric residual volumes had no impact on the incidence of pneumonia. In fact, in the randomized trial, vomiting was increased in the group of patients in whom gastric residual volumes were not assessed, but this did not result in an increase in the incidence of pneumonia.[76]

■ Strategies and Recommendations

Critically ill patients, whose prognosis warrants the intervention, should receive enteral nutrition early in their course if they are malnourished and are expected to be without nourishment for some time. Parenteral nutrition should only be used for patients with chronic gut failure, and it should not be used early. Our practice is to wait for up to 2 weeks to start parenteral nutrition in patients without preexistent malnourishment who do not respond to efforts at enteral feeding. The practice of routinely measuring gastric residual volumes has been shown to have no clinical benefit and may decrease calorie delivery.

CHAPTER 151

Diagnosis and Treatment of Pain, Agitation, and Delirium in the Intensive Care Unit

Niall T. Prendergast
Timothy D. Girard
Nathan E. Brummel

INTRODUCTION

Most patients in intensive care units (ICUs) experience pain, agitation, or delirium at some point during their critical illness. During the last two decades, tremendous growth in knowledge regarding the assessment and management of these syndromes in the ICU has prompted important changes in the practice of intensive care medicine. Validated tools now allow clinicians to quickly and reliably evaluate patients for pain, assess their level of consciousness, and detect delirium. These assessments, in turn, guide clinicians as they choose and titrate therapies targeted to best manage a patient's symptoms. Novel strategies to address pain, agitation, and delirium have recently been investigated. The use of validated tools to diagnose these important clinical syndromes and the use of evidence-based management strategies improve both short- and long-term outcomes. This chapter reviews these assessment tools and describes best practices for management of pain, agitation, and delirium in patients with critical illness.

PAIN IN THE CRITICALLY ILL

Patients with critical illness frequently suffer from pain.[1,2] Because pain is nearly ubiquitous in the ICU and is a common source of agitation in patients with critical illness, clinicians should seek to treat pain first as a means by which to ensure patients are able to maintain an alert and calm state.[3–5] Nevertheless, although effective treatments for pain are widely available, detecting pain in those critically ill patients who are unable to report it is challenging. Prolonged pain in the critically ill is associated with adverse physiologic effects.[6] Because analgesia is most effective when pain is identified and treated early, clinicians should frequently assess patients for pain and treat it when identified.[7]

Assessing Pain in the Critically Ill

Pain is subjective by nature; therefore, a patient's self-report (using a numeric scale or a visual analog scale) is an easy and reliable method to determine its presence. In fact, the Society of Critical Care Medicine (SCCM) recommends that the numeric rating scale be used to assess pain when patients can self-report.[4] Among the critically ill, however, self-reporting is not always possible due to sedation or delirium. In cases where patients cannot self-report their pain, clinicians may view vital signs as indicators of pain, but multiple studies show that vital signs are poor correlates of pain in patients with critical illness.[8–10] Therefore, several instruments have been developed and validated to help clinicians identify and quantify pain in critically ill patients.

The two most widely studied pain assessment tools for use with ICU patients who are unable to report pain are the Behavioral Pain Scale (BPS) and the Critical Care Pain Observation Tool (CPOT).[11,12] Both the BPS and CPOT use nonverbal cues and patient behaviors to establish the presence of pain; these include facial expressions, body movements, and compliance with mechanical ventilation (Table 151-1A,B). Alternatively, a patient's surrogate (e.g., a spouse) may be able to describe behaviors indicative of pain in a particular patient based on the surrogate's prior knowledge of the patient.[13] Finally, in the case where the clinician is unsure if a patient is having pain, a trial of an analgesic medication can be used to assess for a decrease in the suspected pain-related behaviors.[13] Regardless of the assessment method used, it is important to note that assessing for pain among the critically ill is associated with improved clinical outcomes, including optimized analgesic and sedative administration and reduced duration of mechanical ventilation and ICU stay.[14–16]

Treating Pain in the Critically Ill

Comprehensive pain management in the critically ill consists of multimodal pharmacologic therapies (e.g., opioid and nonopioid medications) in combination with nonpharmacologic approaches to ensure adequate analgesia.[5,7]

TABLE 151-1A Critical Illness Pain Observation Tool (CPOT)

Clinical Indicator	Description	Score
Facial expression	Relaxed; no muscular tension observed	0
	Tense; frowning, brow lowering, eye tightening, neck contraction	1
	Grimacing; all previous facial movements plus eye lids tightly closed	2
Body movements	Absence of movements or normal position	0
	Protection; cautious movements, touching/rubbing site of pain, seeking attention through movements	1
	Restlessness/agitation; pulling tube, attempting to sit up, thrashing, not following commands, striking at staff, trying to climb out of bed	2
Muscle tension	Relaxed; no resistance to passive movements	0
	Tense/rigid; resistance to passive movements	1
	Very tense/rigid; strong resistance to passive movements	2
Intubated patients: compliance with the ventilator	Tolerating vent/movement; alarms not activated, easy ventilation	0
	Cough but tolerating; alarms stop spontaneously	1
	Fighting ventilator; blocking ventilation, alarms frequently activated	2
Nonintubated patients: verbalization	Talking in normal tone or no sound	0
	Sighing, moaning	1
	Crying out, sobbing	2

Higher scores indicate greater pain.
Data from Gélinas C1, Fillion L, Puntillo KA, et al. Validation of the critical-care pain observation tool in adult patients. Am J Crit Care. 2006;15(4):420–427 and Payen JF1, Bru O, Bosson JL, et al. Assessing pain in critically ill sedated patients by using a behavioral pain scale. Crit Care Med. 2001;29(12):2258–2263.

TABLE 151-1B Behavioral Pain Scale (BPS)

Item	Description	Score
Facial expression	Relaxed	1
	Partially tightened (e.g., brow lowering)	2
	Fully tightened (e.g., eyelid closing)	3
	Grimacing	4
Upper limb movements	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with mechanical ventilation	Tolerating movement	1
	Coughing but tolerating ventilation for most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

Higher scores indicate greater pain.
Data from Gélinas C1, Fillion L, Puntillo KA, et al. Validation of the critical-care pain observation tool in adult patients. Am J Crit Care. 2006;15(4):420–427 and Payen JF1, Bru O, Bosson JL, et al. Assessing pain in critically ill sedated patients by using a behavioral pain scale. Crit Care Med. 2001;29(12):2258–2263.

Intravenous opioid analgesics, such as fentanyl, morphine, hydromorphone, methadone, and remifentanil, are recommended first-line treatments for acute, nonneuropathic pain among the critically ill. The specific drug choice and dose are determined by the severity of the pain, patient characteristics (e.g., age, renal, and hepatic function), the patient's clinical status, and the properties of the drug (e.g., pharmacokinetics and pharmacodynamics) (Table 151-2).

Nonopioid analgesics (e.g., acetaminophen, ibuprofen, ketamine) may be administered as adjuvant therapies to reduce pain intensity and decrease the overall dose of opioids.[5] Nonpharmacologic interventions such as massage, relaxation techniques, heat or ice application, and music therapy may provide additional analgesic effect.[7] For patients experiencing neuropathic pain, use of gabapentin, carbamazepine, or pregabalin may be added to opioid and nonopioid analgesics.[5]

AGITATION IN THE CRITICALLY ILL

Agitation in critically ill patients is associated with adverse outcomes, such as the removal of life-support devices and danger to the patient or beside staff. Commonly, agitated patients are given sedatives to reduce agitation and prevent harm.[17] It is important to remember, however, that agitation does not equate to "sedation deficiency." Rather, the presence of agitation should prompt the clinician to search for—and treat—an underlying cause, such as pain, hypoxemia, metabolic derangements, developing sepsis, delirium, or withdrawal from alcohol or other drugs. Agitation exists at one extreme of the continuum of consciousness that also includes calm states and states of decreased arousal, such as stupor and coma. This section reviews methods to assess level of consciousness as well as best practices for the treatment of agitation, primarily through the judicious use of sedative medications.

■ Assessing Agitation and Level of Consciousness in the Critically Ill

Several standardized measures can be used to determine level of consciousness in the critically ill. Although these tools are commonly referred to as "sedation-agitation scales," they should be used to evaluate all patients in the ICU, regardless of whether they are receiving sedatives, as they assess patient behaviors and response to verbal or physical stimuli to determine the patient's level of consciousness. The Richmond Agitation-Sedation Scale (RASS) and Riker Sedation-Agitation Scale (SAS) are the most valid and reliable for determining level of consciousness during critical illness (Table 151-3).[4] Unlike the Glasgow Coma Scale (GCS), the RASS and SAS have been validated for use in the setting of ongoing critical illness, even when patients are sedated and/or nonverbal due to placement of an endotracheal tube.[18–20] Regular assessments of level of consciousness can improve detection of changes in neurologic status as well as facilitate and guide delivery of sedatives and other psychoactive medications.

■ Treating Agitation in the Critically Ill

The first step in treating agitation should be to seek out the underlying (and potentially reversible) cause(s). Providing adequate analgesia, treating hypoxemia with supplemental oxygen, correcting electrolyte abnormalities, treating infection, providing reorientation, ensuring an environment conducive to sleep, early mobilization, and treating alcohol and drug withdrawal may eliminate agitation in the appropriate situation. If agitation persists despite measures aimed at addressing the underlying cause, consideration should be given to administration of sedatives.

Recent years have seen a dramatic shift in the strategies used to sedate patients in the ICU. As a result of numerous trials reporting better outcomes among patients managed using protocol-based administration of sedatives compared with those managed without the guidance of a protocol,[21–24] an increasing number of ICUs are adopting algorithmic approaches to the delivery of sedatives to critically ill patients. While many protocols exist, common threads present in each include objective assessment of level of consciousness using a validated tool; prioritization of analgesia over administration of sedatives; targeting lighter (e.g., alert, calm, and comfortable states) rather than moderate or heavy sedation; using intermittent

TABLE 151-2 Pharmacology of Selected Opioid Analgesics

Drug	Equianalgesic Dose	Half-life	Intermittent Dose	Infusion Dose	Adverse Effects/Other Information
Morphine	10 mg	2–3 h	0.01–0.15 mg/kg every 1–2 h	0.07–0.5 mg/kg/h	Accumulates in renal and hepatic failure; hypotension (due to histamine release)
Fentanyl	100 μg	1.5–6 h	0.35–1.5 μg/kg every 0.5–1 h	0.7–10 μg/kg/h	Less hypotension than morphine; accumulates in hepatic failure
Hydromorphone	1.5 mg	3–7 h	10–30 μg/kg every 1–2 h	7–15 μg/kg/h	Accumulates in renal and hepatic failure; use in patients intolerant of morphine or fentanyl
Remifentanil	—	3–10 min	—	Loading dose: 1.5 μg/kg Maintenance dose: 0.6–15 μg/kg/h	No accumulation in hepatic or renal failure

TABLE 151-3 Level of Consciousness Scales: Richmond Agitation-Sedation Scale (RASS) and Riker Sedation-Agitation Scale (SAS)

RASS Level	Label	Description	Label	SAS Score
+4	Combative	Combative, violent, immediate danger to staff, climbing over bedrail, thrashing side to side	Dangerous agitation	7
+3	Very agitated	Pulls to remove tubes or catheters, aggressive, requiring restraint and frequent reminder of limits	Very agitated	6
+2	Agitated	Frequent nonpurposeful movement; fights ventilator	Agitated	5
+1	Restless	Anxious, apprehensive, movements not aggressive; follows commands		
0	Alert and calm	Spontaneously pays attention to caregiver; follows commands	Calm and cooperative	4
−1	Drowsy	Not fully alert, but has sustained awakening to voice (eye opening and contact for >10 s)	Sedated	3
−2	Light sedation	Briefly awakens to voice (eyes open and contact for <10 s)		
−3	Moderate sedation	Movement or eye opening to voice (no eye contact)		
−4	Deep sedation	No response to voice, but movement or eye opening to physical stimuli	Very sedated	2
−5	Unarousable	No response to voice, physical or noxious stimulation	Unarousable	1

Higher (more positive) scores indicate greater agitation.

dosing of medications or daily interruption of sedatives; and relying on nonbenzodiazepine regimens.

Prioritizing Analgesia

As discussed earlier in this chapter, pain is pervasive among critically ill patients and is a frequent reason for agitation. Thus, evaluation and treatment of pain using the techniques described earlier may be sufficient to restore a patient to a calm and alert state. Several studies of sedation protocols that preferentially treated pain before administering sedatives have demonstrated improved patient outcomes,[21,25,26] and current guidelines recommend treatment of pain prior to administration of sedatives.[5]

A dramatic example of the value of pain management prior to administration of sedatives was provided in a randomized trial comparing a control group (sedated primarily with propofol) to patients managed using a strategy of "no sedation."[27] Patients in the intervention arm received morphine for pain first, then haloperidol for agitation, then, if needed, intermittent short-course (i.e., 6-h) administration of propofol. Only after failing this regimen (as indicated by ongoing agitation) did patients in the intervention group receive sedation using a more conventional propofol- and midazolam-based sedation strategy. Patients managed with the "no sedation" strategy had significantly better outcomes than those in the control group, spending more time off mechanical ventilation and experiencing earlier discharge from the ICU and hospital.

A larger multicenter trial, which sought to determine if the "no sedation," analgesia-first strategy improves survival did not find significant differences in mortality, ICU length of stay, or ventilator-free days in treatment groups but did find that some secondary endpoints, including days without delirium or coma and major thromboembolic events at 90 days, were improved for those in the "no sedation" group.[28] Whereas some of the results of this multicenter trial do not corroborate those from the single-center study, several key points should be noted. First, challenging the notion that all patients on mechanical ventilation need sedation is that only around 20% of patients in the "no sedation" groups of both trials required treatment with continuous sedatives. Second, the need for sedation can be assessed multiple times daily, as was the case in this study where the need for sedation in the intervention group was assessed every 6 h.

Intermittent Versus Continuous Dosing of Sedatives

As demonstrated in the aforementioned trials of "no sedation" strategies, which prioritized use of intermittent morphine and haloperidol, many analgesic and sedative medications can be delivered intermittently (via bolus) rather than continuously (via infusions). The latter has been the most common method of sedation used in ICUs,[16] with routine use of continuous infusions reflecting the fact that most early studies of sedation in the ICU utilized continuous infusion strategies. Nevertheless, continuous infusion of analgesics and sedatives can lead to accumulation of the infused drug, resulting in delayed clearance and prolonged effects. Moreover, continuously infused medications are readily titrated to higher doses to treat agitation, but often the infusion may not be rapidly titrated to lower doses once the acute agitation has been controlled. These factors may combine to lead to adverse outcomes, including prolongation of mechanical ventilation and ICU and hospital stays. For example, one study showed that patients who were managed using intermittent doses of benzodiazepines rather than benzodiazepine infusions were extubated sooner, were discharged from the ICU and hospital earlier, and had lower rates of reintubation compared with those who received continuous sedation.[29] Based on these findings, the same group developed a sedation protocol that prioritized analgesia first, then intermittent bolus sedatives, before allowing continuous infusions of sedatives. In a randomized controlled trial, this sedation protocol resulted in earlier extubation and discharge from the ICU and hospital compared with management without a sedation protocol.[21]

When considering the evidence regarding intermittent versus continuous dosing of sedatives in the ICU, it should be noted that not all trials favored intermittent dosing. The choice of drug is also an important determinant of outcomes. Although intermittent dosing of benzodiazepines results in better outcomes than continuous benzodiazepine infusions, avoidance of benzodiazepines altogether, even if this means using continuous propofol, will improve outcomes further, as evidenced by trials comparing benzodiazepine sedation with nonbenzodiazepine alternatives.[30]

■ Avoiding Benzodiazepines

Although early trials of sedation protocols[21] utilized benzodiazepines as the sedative of choice (when an analgesia-only approach did not adequately treat agitation), more recent trials have consistently shown that benzodiazepines lead to worse outcomes than alternative sedative agents. As the result of these studies, nonbenzodiazepine sedatives are preferred over benzodiazepines for sedation in patients with critical illness.[5]

In the late 1980s and 1990s, more than a dozen randomized trials found that sedation with propofol led to better outcomes than sedation with benzodiazepines.[31] However, the results did not lead to changes in standard of care, in part because control groups used continuously infused midazolam rather than intermittent boluses. In fact, clinical guidelines published in 2002 recommended lorazepam as the drug of choice for sedating patients in the ICU.[32] Therefore, a key randomized trial was conducted to compare intermittent lorazepam with continuous propofol for the sedation of mechanically ventilated patients in the ICU.[30]

Patients in both groups were managed using daily interruption of sedatives. Despite the avoidance of continuous infusions in only the lorazepam group (since propofol generally requires delivery by continuous infusion when used in the ICU), patients sedated with propofol spent on average 5 days fewer days on mechanical ventilation. These findings were consistent with nearly every other trial comparing propofol with benzodiazepines, suggesting that continuous sedation with shorter-acting agents, such as propofol, when interrupted daily, improves outcomes compared with intermittent doses of benzodiazepines.

Benzodiazepine-based sedation has been compared with other sedative agents; the alternatives to benzodiazepines have been found superior. Numerous randomized trials have compared sedation with benzodiazepines with dexmedetomidine among mechanically ventilated patients in the ICU; all found that patients randomized to sedation with dexmedetomidine had better outcomes—for example, less delirium and earlier extubation—than those sedated with benzodiazepines.[33–39]

Similarly, in three trials randomizing mechanically ventilated patients to remifentanil-based sedation versus benzodiazepine-based sedation, those sedated with benzodiazepines had worse outcomes.[31–33] The pharmacologic properties of these and other agents commonly used for sedation in the ICU are presented in Table 151-4.

■ Choice of Sedative

As a result of the data presented above, first-line use of benzodiazepines for sedation is no longer recommended; guidelines recommend either propofol or dexmedetomidine.[5] The choice between those two agents has largely been a matter of clinician preference. Three trials, including two published since the 2018 PADIS guidelines, have shed additional light on this question.

The DahLIA study, published in 2016, randomized 74 patients in whom extubation was considered inappropriate due to agitation and delirium to either dexmedetomidine or placebo. Dexmedetomidine was found to increase the number of hours alive and off of mechanical ventilation at 7 days, as compared with placebo.[40]

The 2019 SPICE-III study analyzed 3904 mechanically ventilated patients randomized to either dexmedetomidine as a primary sedative or to usual care (primarily propofol, although midazolam and the combination of midazolam and propofol also were used). There was no difference in mortality, which was the primary outcome, but the dexmedetomidine group had a significantly greater number of days alive and free of delirium or coma.[41]

Most recently, the 2021 MENDS2 study randomized 422 mechanically ventilated patients with sepsis to sedation with either propofol or dexmedetomidine. The study found no difference in any of its endpoints, including mortality, days free of delirium or coma, and long-term neurocognitive dysfunction, between the two groups.[42] Evidence thus suggests that while dexmedetomidine may be useful in particular situations, for example when agitated delirium is a barrier to extubation, outcomes associated with these two drugs are similar.

■ Targeting Light Sedation and Daily Interruption of Sedatives

Regardless of which medications are used to provide analgesia and sedation, they should be given in the smallest doses necessary to treat pain and agitation while allowing patients to maintain wakefulness—that is, light, rather than heavy, sedation should be the goal. Sedation protocols not only prioritize analgesics and intermittent sedatives over continuous infusions, they may also target light sedation (measured using a sedation scale) over moderate or heavy sedation.[21] Evidence in support of targeting lighter sedation stems from both observational and clinical trial data showing those patients who are treated with light sedation have better outcomes. Three multinational, observational cohort studies show that patients who were maintained at a level of consciousness that was RASS −2 or more alert during the first 48 h of an ICU admission had greater 6-month survival than those who were maintained at deeper levels (e.g., RASS −3 or more sedated), regardless of the sedative medication(s) used.[43–45] Other studies of patients receiving mechanical ventilation

TABLE 151-4 Selected Sedative Agents

Drug	Mechanism of Action	Half-life	Intermittent Dose	Infusion Dose	Adverse Effects
Propofol	GABA$_a$ agonist	40 min	0.2–0.6 mg/kg	5–80 μg/kg/min	Hypotension, respiratory depression, pancreatitis, hypertriglyceridemia, PRIS
Dexmedetomidine	CNS α-2 agonist	$T_{1/2}$ a = 6 min $T_{1/2}$ b = 2 h	—	0.2–1.5 μg/kg/h	Hypotension and bradycardia (with loading dose); loss of airway reflexes
Haloperidol	CNS D_1 and D_2	18 h	2–10 mg	0.04–0.15 mg/kg/h	QTc prolongation; extrapyramidal symptoms; dystonia
Midazolam	GABA$_a$ agonist	3 h	0.02–0.08 mg/kg	0.04–0.2 mg/kg/h	Respiratory depression; hypotension; accumulates in renal and hepatic failure
Lorazepam	GABA$_a$ agonist	8 h	0.02–0.04 mg/kg	0.01–0.1 mg/kg/h	Respiratory depression; hypotension; propylene glycol–related acidosis; nephrotoxicity

PRIS, propofol-related infusion syndrome; $T_{1/2}$ a, distribution half-life; $T_{1/2}$ b, elimination half-life; QTc, corrected QT interval.

who were randomized to light versus moderate or heavy sedation also found that those managed with light sedation were extubated sooner, had shorter ICU stays, and had fewer disturbing memories of the ICU, compared with those managed with heavier sedation.[46]

Whenever given, sedatives should be held each day that basic safety criteria are met so that the clinician may assess the need for and optimal doses of analgesic and sedative medications required to maintain patient comfort and alert mental status. This period of daily interruption of sedatives, also referred to as a daily "wake-up," "sedation holiday," or "spontaneous awakening trial," led to significantly better outcomes in two seminal randomized trials. In one trial,[23] patients managed with daily interruption of sedatives had shorter durations of mechanical ventilation and shorter stays in the ICU. In another,[22] those managed using this strategy not only were extubated earlier than those in the control group, they also were discharged earlier from the ICU and hospital; furthermore, their 1-year mortality was 14% lower than that observed in the control group. The latter trial paired daily interruption of sedatives or daily spontaneous awakening trials with daily spontaneous breathing trials as part of a strategy referred to as "Wake-up and Breathe" (Fig. 151-1).

Although most sedation trials have examined either targeted light sedation or daily interruption of sedatives, the SLEAP randomized trial studied whether combining the two strategies yielded improved

Acute cardiac arrhythmia

Figure 151-1 Wake-up and breathe flowchart. Each day patients should be assessed for safety criteria to perform a spontaneous awakening trial (SAT). If the safety screen is passed, all sedating medications are held until the patient is RASS –3/SAS 3 or more alert. The patient is then screened for the presence of safety criteria to undergo a spontaneous breathing trial (SBT). As with the SAT, if the SBT safety screen is passed, the patient should undergo an SBT. If the patient meets any of the failure criteria, either sedation or ventilatory support is resumed and the trial begins anew the next day. Combining daily SATs with daily SBTs is associated with shorter duration of mechanical ventilation, ICU length of stay, and a 14% improvement in mortality 1 year following critical illness. *(Reproduced with permission from © icudelirium.org and Vanderbilt University, all rights reserved.)*

outcomes over using only targeted light sedation.[47] Patients randomized to targeted light sedation with daily interruption had similar outcomes to those managed with targeted light sedation alone. While these data suggest that there is no difference between these two sedation strategies, it is important to note that those in the daily interruption group were exposed to higher doses of benzodiazepines and opiates than those in the targeted light sedation group. This result is counter to prior studies of daily sedation interruption, which found this strategy reduced overall exposure to sedatives and showed improved outcomes. Although the SLEAP trial does not rule out the possibility that daily interruption of sedatives plus targeted light sedation is equivalent to a targeted light sedation strategy alone, further study is needed comparing daily sedative interruption in a way that lowers exposure to sedatives to targeted light sedation. Nevertheless, a key take-home message from the SLEAP study is that if sedation strategies do not reduce overall exposure to sedatives, patients are less likely to benefit.

In summary, modern sedation practices (1) place an emphasis on targeted light sedation, as assessed using a validated tool for determining level of consciousness; (2) prioritize treating pain first using intravenous opiates and then, if the patient requires additional sedation, intermittent and sometimes continuous doses of a nonbenzodiazepine sedative; and (3) routinely incorporate daily interruption of drugs, maintaining a “light” level of sedation (Fig. 151-2).

DELIRIUM IN THE CRITICALLY ILL

Delirium during critical illness represents an acute form of brain dysfunction. Because it is frequently observed in the ICU, this

Figure 151-2 Example pain, agitation, and delirium protocol. In this example protocol, pain is first assessed, and if present, IV analgesia is given first with intermittent dosing. If more than three boluses are needed in an hour, an infusion of fentanyl is started. The patient’s level of consciousness is monitored using the Richmond Agitation-Sedation Scale (RASS) or the Sedation-Agitation Scale (SAS), with a default of alert/calm or drowsy (RASS –0 to –1 or SAS 4). If the patient is agitated despite adequate pain control, an infusion of either propofol or dexmedetomidine is preferentially used. Midazolam is begun only if the patient is withdrawing from alcohol, has a propofol intolerance, or has received propofol for >96 h. If the patient is more deeply sedated than RASS –1 or SAS 3, sedatives and analgesics are held until the patient is again alert and calm. If needed, analgesics and sedatives are resumed at half (or less) of the previous infusing dose. Each day patients undergo coordinated spontaneous awakening and breathing trials (SAT + SBT). Finally, patients are screened for delirium using either the Intensive Care Delirium Screening Checklist (ICDSC) or the Confusion Assessment Method for the ICU (CAM-ICU), and if delirium is present a cause is first sought with nonpharmacologic and pharmacologic interventions begun if no reversible cause is identified. *(Reproduced with permission from © icudelirium.org and Vanderbilt University, all rights reserved.)*

syndrome was previously considered by many to be an expected, inconsequential complication of critical illness, often referred to as "ICU syndrome."[48] Multiple studies have shown, however, that delirium is associated with numerous adverse short- and long-term outcomes. Yet it often goes unrecognized, in part because the most common presentation is that of hypoactive (quiet) delirium. This section reviews the definition of delirium, key features and differences from other forms of altered mental status, the current understanding of delirium's pathophysiologic basis, risk factors for development, bedside tools specifically designed to assess delirium in the ICU, the short- and long-term consequences associated with delirium, and methods for preventing and treating delirium.

■ Definition of Delirium

The American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders* fifth edition (DSM-5)[49] diagnostic criteria for delirium are (1) a disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment); (2) development of the disturbance over a short period of time (usually hours to a few days), in which the development represents a change from baseline in attention and awareness and which tends to fluctuate in severity during the course of a day; (3) an additional disturbance in cognition (e.g., memory deficit, disorientation, language, visual–spatial ability, or perception); (4) the disturbances in criteria (1) and (2) are not better explained by another pre-existing, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma; and (5) there is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiologic consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple etiologies.

Many signs and symptoms commonly observed in delirium, such as disturbance in the sleep–wake cycle, psychomotor agitation or decreased psychomotor activity, hallucinations, delusions, and perceptual disturbances, support the diagnosis but are neither sufficient nor required to make the diagnosis. Because these symptoms may be caused by other neurocognitive disorders, delirium is sometimes mistaken for other disorders, particularly dementia. Table 151-5 summarizes differences between delirium and dementia.

Historically, a large number of terms have been used to describe delirium in ICU patients, including encephalopathy, ICU psychosis, ICU syndrome, toxic confusional state, brain failure, subacute befuddlement, postoperative psychosis, and septic encephalopathy.[50] Use of these terms can lead to misunderstanding by practitioners, and certain terms, including ICU syndrome and ICU psychosis, can imply that the syndrome is an expected part of an ICU stay.[48,50,51] Therefore, regardless of the underlying etiology, the standardized term *delirium* should be used to describe a patient who meets the DSM criteria for delirium, with the suspected underlying etiology then used to describe the delirium (e.g., use the term "delirium due to sepsis" rather than "septic encephalopathy").[48,50,51]

■ Prevalence and Subtypes of Delirium

Delirium is highly prevalent among mechanically ventilated patients in ICUs (60%–80% develop delirium at some point during their ICU stay),[22,33,34,52–54] and also commonly affects nonventilated patients in the ICU setting (20%–40% are affected).[55–58] Delirium can be classified into subtypes according to the motor activity of the patient; these subtypes include *hyperactive, hypoactive*, and *mixed delirium*. Patients with hyperactive delirium are agitated and restless, and they may describe or respond to hallucinations and/or delusions. Those with the hypoactive subtype are calm and lethargic, and they often have decreased spontaneous movements. Finally, the mixed delirium subtype presents at different times with features of both hyperactive and hypoactive delirium. The most common motor subtypes observed in the ICU are mixed and hypoactive, with purely hyperactive delirium accounting for only a small percentage of cases of delirium.[59,60]

Not only is hypoactive delirium a common presentation of delirium, but preliminary data also suggest that those with hypoactive delirium may have worse outcomes. In a prospective cohort study of 582 survivors of critical illness, those with a longer duration of hypoactive delirium had worse global cognition and worse executive function following their critical illness.[61] In contrast, the duration of hyperactive delirium showed no such association, although the small number of patients experiencing hyperactive delirium means that an association with adverse long-term outcomes cannot be ruled out. As data continue to accumulate that the length of time a patient is delirious is associated with worse clinical outcomes, the fact that a majority of delirious patients in the ICU have mixed or

TABLE 151-5 Distinguishing Delirium from Dementia

Syndrome	Onset	Course	Diagnostic Features	Associated Features	Common Causes
Delirium	Acute (hours to days)	Fluctuating	Disturbance in attention and awareness Memory impairment, disorientation, or language impairment	Sleep/wake disturbances Extremes in psychomotor activity Emotional disturbances (e.g., fear, anxiety, depression, irritability, euphoria, apathy)	Acute medical illnesses Medications Substance intoxication or withdrawal Multifactorial
Dementia	Insidious (months to years)	Progressive	Memory impairment, plus one of the following: – Aphasia – Apraxia – Agnosia – Impaired executive functioning Impairments must be severe enough to cause impairments in social or occupational functioning and represent a decline from baseline	Visuospatial impairment Little/no awareness of memory impairment Gait disturbance Anxiety/mood/sleep disturbances	Dementia of Alzheimer type Vascular dementia Chronic medical conditions (Pick disease, HIV, stroke, head injury)

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th Edition. Washington, DC: American Psychiatric Association; 2013.

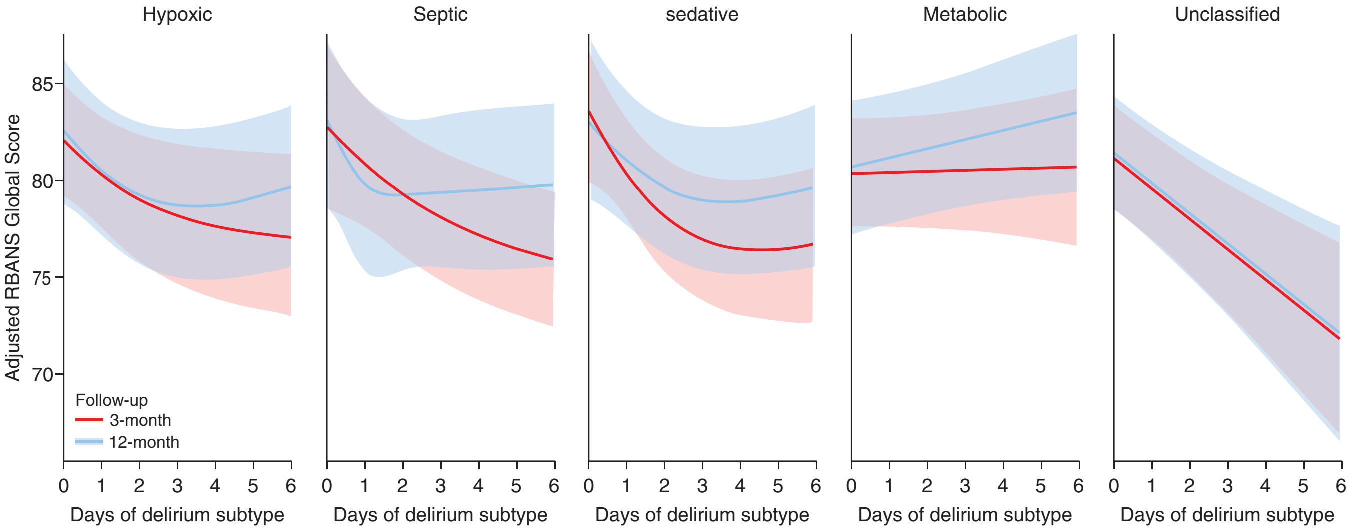

Figure 151-3 Associations between delirium phenotypes and long-term cognitive function. These figures show the associations between the number of days of different delirium phenotypes characterized by hypoxemia, sepsis, sedation exposure, metabolic abnormalities (e.g., renal failure or hepatic failure), or delirium characterized by none of these. With the exception of metabolic delirium, the duration of all phenotypes of delirium were associated with worse cognitive function at 3 months *(red lines)* and 12 months *(blue lines)*. *Solid lines* represent the association, and *shading* represents the 95% confidence interval of the association. *(Reproduced with permission from Girard TD, Thompson JL, Pandharipande PP, et al. Clinical phenotypes of delirium during critical illness and severity of subsequent long-term cognitive impairment: a prospective cohort study. Lancet Respir Med. 2018;6(3):213–222.)*

hypoactive subtypes is an important point for clinicians, as the presence of these subtypes of delirium is frequently overlooked.[62]

Delirium can also be classified into subtypes by its presumptive cause. One study divided 740 delirious patients into hypoxic (those patients with hypoxemia or shock), septic (those meeting criteria for sepsis), metabolic (those with uremia, hypoglycemia, hepatic dysfunction, or hyper/hyponatremia), sedative-associated (those who had received a sedative in the preceding 24 h), or unclassified (none of the above) delirium.[63] This study found that all delirium phenotypes except for metabolic delirium were associated with worse cognitive function at 12 months after discharge (Fig. 151-3). These data suggest that there are few benign causes of delirium and that even delirium that occurs in response to sedation, which is intended to reduce level of consciousness, is associated with adverse outcomes and should therefore be avoided whenever possible.

■ Risk Factors for Delirium

Delirium during critical illness is most often a multifactorial syndrome that develops when a vulnerable patient encounters a sufficiently strong insult or insults to precipitate onset of the syndrome,[64] although it is possible for a patient without preexisting vulnerabilities to become delirious during a critical illness. Typically, a patient with high baseline vulnerability, such as an elderly patient with underlying dementia, may require only a mild insult, such as pneumonia, but a younger patient without pre-existing cognitive impairment, that is, low baseline vulnerability, may require multiple strong insults, such as sepsis, mechanical ventilation, sedation with benzodiazepines, and immobilization. This scenario is not uncommon, given that critically ill patients are exposed on average to 11 risk factors for delirium.[65]

Risk factors for delirium can be thought of as predisposing factors, including baseline patient characteristics and premorbid conditions, and precipitating factors, such as those related to critical illness and treatments in an ICU. Baseline risk factors include older age, pre-existing cognitive impairment or dementia, use of alcohol or tobacco, hypertension, visual or hearing impairment, and APOE4 genotype.[53,66–70]

A number of precipitating factors are linked to development of delirium during critical illness, including high severity of illness, admission to an ICU for a medical illness (as opposed to a surgically treated condition), receipt of mechanical ventilation, high number of infusing medications, hypotension, acidosis, fevers, sepsis, electrolyte abnormalities, liver function test abnormalities, blood transfusion, and anemia.[54,66–69,71,72] Whereas each of these risk factors results from a patient's critical illness, factors associated with treatment may also increase risk. Precipitating risk factors associated with treatment in an ICU include immobility, presence of gastric tubes, bladder catheters, arterial lines, sedative and analgesic medications, particularly benzodiazepines, and those factors related to the overall ICU environment, including lack of daylight, isolation, lack of visitors, and sleep disturbances.[72,73]

■ Pathophysiology of Delirium

Delirium pathophysiology, although incompletely understood, likely represents a final common pathway from many different—perhaps interrelated—pathophysiologic mechanisms, including neurotransmitter imbalances, inflammation, aberrant stress responses, and impaired cerebral perfusion. It is thought that imbalances in the neurotransmitters that maintain arousal and sleep–wake cycles—notably acetylcholine and dopamine—are primary drivers of delirium.[74,75] Impaired central cholinergic functioning can result from derangements occurring anywhere along the pathway from acetylcholine production to its release and action on postsynaptic receptors. Acetylcholine deficiency or blockade has been associated with delirium, as has dopamine excess, likely through dopamine receptor regulation of acetylcholine activity.[75–77] Other neurotransmitters, such as gamma-aminobutyric acid (GABA), norepinephrine, serotonin, glutamate, and melatonin, also have been hypothesized to play a role in delirium, although the contribution of these neurotransmitters in the development of delirium is not well understood.[74–79]

Alterations in precursor molecules to neurotransmitters, such as dopamine, norepinephrine, serotonin, and melatonin—in particular, the large neutral amino acids (LNAAs)—also have been hypothesized to be involved in the pathogenesis of delirium.[80] LNAAs, which include leucine, valine, tryptophan, tyrosine, and phenylalanine, compete for transfer across the blood–brain barrier via a single transport receptor, such that increased transport of one LNAA results in decreased transport of others. Thus, the concentration of neurotransmitters in the CNS is related to changes in serum concentrations of LNAAs, and changes in these concentrations have been associated with delirium during critical illness.[81–83]

Systemic inflammation, which is very common during critical illness, also is thought to play a role in development of delirium. Inflammatory molecules such as interleukin-1β (IL-1β), IL-6, IL-8, TNF-α, and prostaglandins, and blood-borne molecules such as lipopolysaccharide, are released in response to infection, tissue damage, and surgery. These molecules interact with the brain via direct autonomic neural pathways, second-messenger systems, and active transport across the blood–brain barrier, and through disruptions in the blood–brain barrier, resulting in neuroinflammation.[84–87] Neuroinflammation triggers CNS production of additional inflammatory cytokines and metalloproteinases, release of reactive oxygen species, and expansion and activation of microglia, resulting in alterations in CNS perfusion, impaired neurotransmitter production, and derangements in oxidative metabolism, ultimately leading to neuronal damage and cell death.[85–87] Neuronal death results in a functional disconnect between neuroanatomic structures, culminating in the neurobehavioral changes observed in delirium.[79,85]

■ Screening Tools for Delirium

Since many delirious patients are lethargic or calm, rather than agitated, delirium in the ICU is overlooked nearly 70% of the time.[62] Thus, expert guidelines recommend that all patients in an ICU be routinely monitored using a well-validated delirium-screening tool.[5]

Two screening tools that were developed specifically for assessment of critically ill adult patients, the Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC), have been the most rigorously validated and widely implemented and, thus, are recommended in expert guidelines.[5] Validated before the release of DSM-5[49] criteria, both the CAM-ICU and the ICDSC were compared in validation studies with expert psychiatric examinations applying the DSM-IV[88] criteria for delirium and were found to have high sensitivity and specificity, as well as excellent interrater reliability when performed by ICU physicians and nurses.[52,57,89–93] Both screening tools identify features of delirium that remain part of the DSM-5 definition, such that the tools are considered current and valid in the DSM-5 era.

With either the CAM-ICU or the ICDSC, the first step when assessing for delirium is to assess the patient's level of arousal/consciousness (see "Assessing Agitation and Level of Consciousness in the Critically Ill," above); as stated in the DSM-5, a patient cannot be assessed for delirium when comatose. In validation studies of the CAM-ICU, this was operationalized by determining that patients were arousable to voice (e.g., RASS −3 or more awake) before proceeding with the CAM-ICU assessment. Similarly, the ICDSC excludes patients in coma or stupor from delirium assessment. Once level of consciousness is assessed, the second step in the delirium evaluation is to assess the content of consciousness using either the ICDSC or the CAM-ICU.

The CAM-ICU was developed based on the full Confusion Assessment Method[94] but tailored to the specific needs of patients in the ICU (e.g., it can be performed in both nonintubated and intubated patients, even in the setting of sedation, as long as the patient is not comatose). During what is typically a 1- to 2-min evaluation, the CAM-ICU assesses four key features of delirium: (1) acute change or fluctuation in mental status, (2) inattention, (3) altered level of consciousness, and (4) disorganized thinking.[52,90] The CAM-ICU is positive—that is, the patient is considered to have delirium—if features 1 and 2 are present and *at least* feature 3 or 4 is present. See Fig. 151-4 for instructions on how to assess each feature in the CAM-ICU. This tool has been translated into more than 30 different languages, and many of these translated versions have been validated.[95]

The ICDSC is an eight-item checklist of delirium symptoms assessed over an 8- to 24-h period. Providers (typically the bedside nurse) monitor patients for the symptoms on the checklist during that period of time (e.g., during a nursing shift) and mark items on the checklist as they are observed. The symptoms include altered level of consciousness, inattention, disorientation, hallucinations/delusions/psychosis, psychomotor agitation or retardation, inappropriate speech or mood, sleep/wake disturbances, and fluctuation of symptoms. One point is given for each symptom observed; a score of four or greater indicates delirium (Table 151-6).

■ Outcomes Associated with Delirium

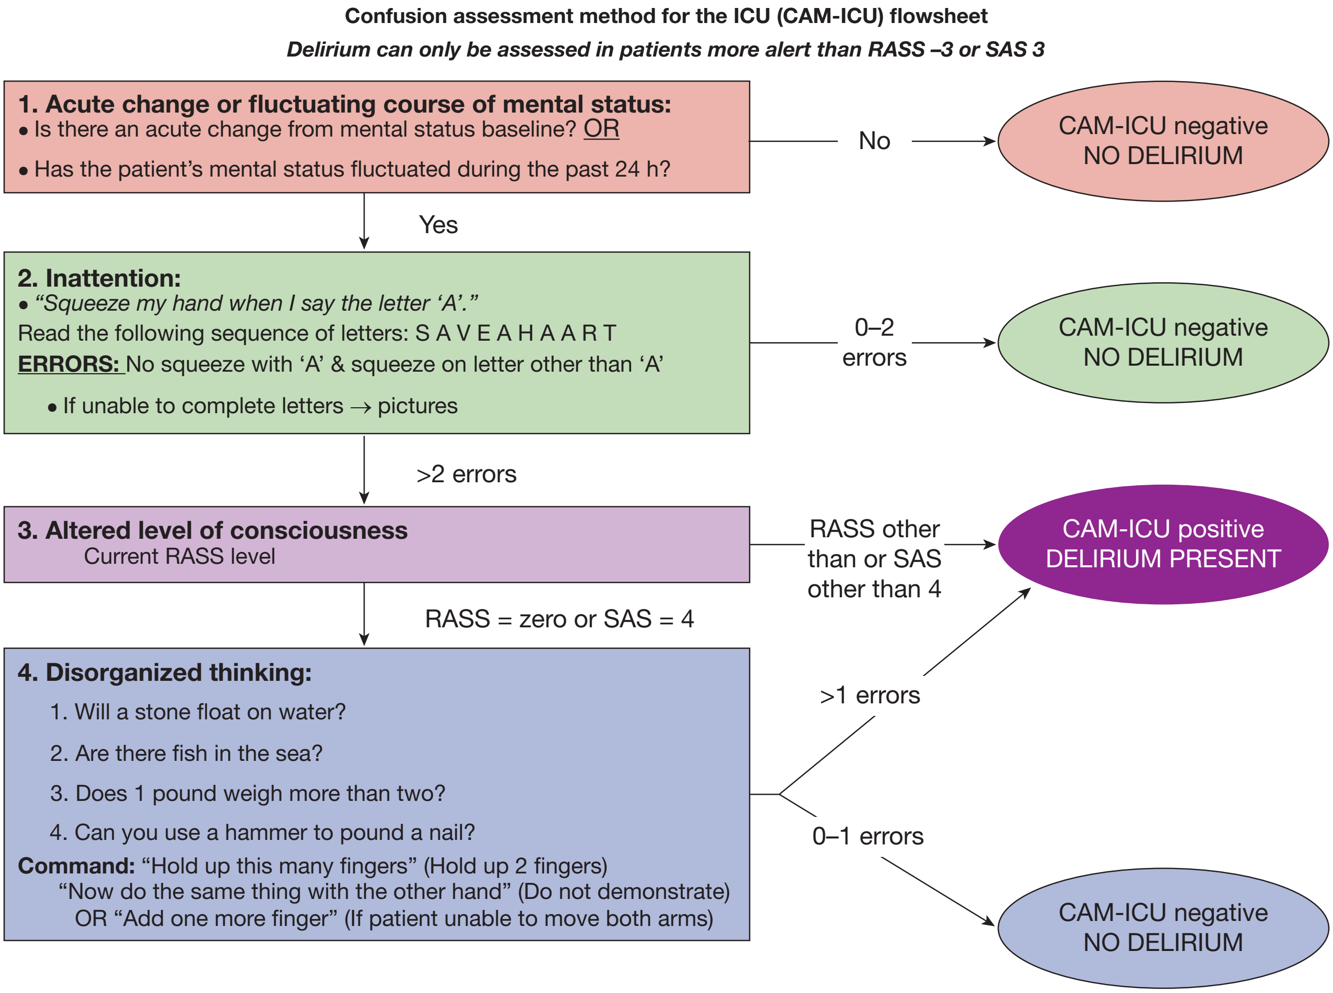
In both the short and long term, patients who suffer from delirium are at risk for several adverse outcomes. Within the context of the acute critical illness, patients who are delirious are more likely to remove catheters and endotracheal tubes, require physical restraints, and have prolonged mechanical ventilation.[66,96,97] In addition, compared with those who do not become delirious, these patients are at higher risk for longer stays in the ICU and hospital, higher healthcare costs, and discharge to locations other than home.[52,69,97–101]

The adverse outcomes associated with delirium do not end at the time of hospital discharge. In two separate prospective cohort studies, each additional day a patient was delirious in the ICU was associated with a 10% increase in the hazard of death at 6 or 12 months following hospital discharge.[102,103] A meta-analysis of 42 different ICU studies similarly found that ICU delirium was associated with a roughly twofold increase in the odds of mortality.[104] In addition, two separate cohort studies have identified duration of delirium as a strong independent predictor of long-term cognitive impairment, with longer delirium durations in the ICU associated with poorer cognitive performance a full year after discharge.[105,106] Additionally, longer durations of multiple delirium phenotypes (including septic, hypoxic, and sedative-associated delirium) were associated with worse long-term cognitive outcomes.[63] Finally, one additional study noted that duration of delirium during critical illness was also associated with activities of daily living among survivors of critical illness, with prolonged delirium predicting disability during long-term follow-up.[107]

■ Preventing Delirium

Preventing delirium from developing during a patient's ICU stay can be difficult because at the time of the patient's ICU admission, acute organ failures (often including delirium) are already present. Nevertheless, preventative measures may be beneficial, since some patients do not develop delirium until several days into their ICU stay. Additionally, because the duration of delirium is also associated with adverse outcomes, including cognitive impairment, physical disability, and death, measures that may shorten the duration of delirium should be implemented. Although not all risk factors for delirium can be avoided, three risk factors common in the ICU—exposure to sedative and analgesic medications, immobility, and sleep deprivation—have been targeted by interventions designed to prevent delirium; a number of studies have shown that these interventions are associated with reductions in delirium.

Benzodiazepines are consistently associated with the development of delirium in patients in the ICU and, therefore, serve as an easily modifiable risk factor. In studies of medical, surgical, cardiac, trauma, and burn patients, higher doses of benzodiazepines have been independently associated with higher risk for delirium.[33,67,108,109] Based on these data, a number of interventions



Confusion assessment method for the ICU (CAM-ICU) flowsheet

Delirium can only be assessed in patients more alert than RASS –3 or SAS 3

1. Acute change or fluctuating course of mental status:
- Is there an acute change from mental status baseline? OR
- Has the patient's mental status fluctuated during the past 24 h?

2. Inattention:
- *"Squeeze my hand when I say the letter 'A'."*

Read the following sequence of letters: S A V E A H A A R T

ERRORS: No squeeze with 'A' & squeeze on letter other than 'A'
- If unable to complete letters → pictures

3. Altered level of consciousness
Current RASS level

4. Disorganized thinking:
1. Will a stone float on water?
2. Are there fish in the sea?
3. Does 1 pound weigh more than two?
4. Can you use a hammer to pound a nail?

Command: "Hold up this many fingers" (Hold up 2 fingers)
"Now do the same thing with the other hand" (Do not demonstrate)
OR "Add one more finger" (If patient unable to move both arms)

No
CAM-ICU negative NO DELIRIUM
Yes
0–2 errors
CAM-ICU negative NO DELIRIUM
>2 errors
RASS other than or SAS other than 4
CAM-ICU positive DELIRIUM PRESENT
RASS = zero or SAS = 4
>1 errors
0–1 errors
CAM-ICU negative NO DELIRIUM

Figure 151-4 The Confusion Assessment Method for the ICU (CAM-ICU). The CAM-ICU assesses for the four features of delirium. Feature 1 is an acute change in mental status or a fluctuating mental status *(orange box)*, feature 2 is inattention *(green box)*, feature 3 is altered level of consciousness *(purple box)*, and feature 4 is disorganized thinking *(blue box)*. A patient screens positive for delirium if features 1 and 2 and either feature 3 or feature 4 are present. *(Reproduced with permission from copyright © 2002, E. Wesley Ely, MD and Vanderbilt University.)*

intended to reduce exposure to benzodiazepines have been investigated. Sedation of mechanically ventilated patients using dexmedetomidine, for example, rather than benzodiazepines, reduced daily risk of delirium in three major randomized trials.[33,34,41] In addition, in one study addressing avoidance of benzodiazepines as one part of a multicomponent quality-improvement program designed to reduce delirium risk, researchers found a significant increase in days patients spent without delirium.[110]

Opioid analgesic medications have also been associated with development of delirium in some studies, but the relationship between opioids and delirium is not as straightforward as the one between benzodiazepines and delirium. This difference likely relates to the dual effects of opioids. For example, when opioids are used to heavily sedate patients, their use is associated with an increased risk of delirium.[68,69,71] When opioids are used primarily to relieve pain rather than to sedate, such as in patients with trauma or burns, the risk of delirium is reduced.[54,108,111] A recent large observational study, however, found that opioid use was associated with a higher risk of developing delirium, even in the presence of pain.[112] Further study of whether opioid-sparing analgesic regimens can be used to prevent delirium are needed to definitively answer this important question.

Immobility, particularly due to the use of physical restraints, is a strong risk factor for the development of delirium among both non-ICU hospitalized and critically ill patients.[64,72] Studies in which early mobilization is promoted among critically ill patients have found that it reduces delirium.[113–116] For example, a 104-patient multicenter randomized trial of mechanically ventilated patients in the medical ICU who were randomized to early physical and occupational therapy or usual care (i.e., delayed physical therapy) found that those who received early physical and occupational therapy spent, on average, 2 fewer days in delirium than those in the control group.[113] A second 200-patient, multicenter randomized trial of surgical ICU patients that compared an early, goal-directed mobility intervention to usual care found that those in the early mobility group experienced 3 more days alive without delirium.[117]

Critically ill patients frequently suffer sleep deprivation. In fact, studies suggest that normal sleep rarely, if ever, occurs during acute respiratory failure requiring mechanical ventilation in the ICU; in one study, only a small percentage of the sleep observed was restorative (REM) sleep, and nearly half occurred during daytime hours.[118] In light of these data and the connection between sleep deprivation and delirium outside the ICU, investigators studied the effect of earplugs in a randomized trial of patients in ICUs and found significant reductions in incidence of delirium.[119] Using a multicomponent intervention that reduced nocturnal lights and noises and provided eye masks, earplugs, and pharmacologic sleep aids, others observed an increase in the number of days free from delirium or coma.[120,121]

Pharmacologic prevention of delirium has generally been shown not to be effective. For example, among nearly 1800 ICU patients at high risk of delirium who were randomized to receive either

TABLE 151-6 The Intensive Care Unit Delirium Screening Checklist (ICDSC)

1. **Altered level of consciousness** Choose **ONE** from A–E

Note: May need to reassess patient if recent administration of sedation therapy

- A. Exaggerated response to normal stimulation SAS = 5, 6, or 7 Score 1 point
- B. Normal wakefulness SAS = 4 Score 0 points
- C. Response to mild or moderate stimulation SAS = 3 Score 1 point
  (follows commands) **Score 0 if LOC related to recent sedation/analgesia**
- D. Response only to intense and repeated stimulation (e.g., loud voice and pain) SAS = 2 **Stop assessment**
- E. No response SAS = 1 **Stop assessment**

2. **Inattention** Score 1 point for any of the following abnormalities:

- A. Difficulty in following commands OR
- B. Easily distracted by external stimuli OR
- C. Difficulty in shifting focus

Does the patient follow you with their eyes?

3. **Disorientation** Score 1 point for any one obvious abnormality:

- A. Mistake in either time, place, or person

Does the patient recognize ICU caregivers who have cared for him/her and not recognize those that have not? What kind of place are you in? (list examples)

4. **Hallucinations or delusions** Score 1 point for either:

- A. Equivocal evidence of hallucinations or a behavior due to hallucinations (Hallucination = perception of something that is not there with NO stimulus) OR
- B. Delusions or gross impairment of reality testing (Delusion = false belief that is fixed/unchanging)

Any hallucinations now or over past 24 h? Are you afraid of the people or things around you?

(fear that is inappropriate to clinical situation)

5. **Psychomotor agitation or retardation** Score 1 point for either:

- A. Hyperactivity requiring the use of additional sedative drugs or restraints to control potential danger (e.g., pulling IV lines out or hitting staff) OR
- B. Hypoactive or clinically noticeable psychomotor slowing or retardation

Based on documentation and observation over shift by primary caregiver

6. **Inappropriate speech or mood Score 1 point for either:**

- A. Inappropriate, disorganized, or incoherent speech OR
- B. Inappropriate mood related to events or situation

Is the patient apathetic to current clinical situation (i.e., lack of emotion)?

Any gross abnormalities in speech or mood? Is patient inappropriately demanding?

7. **Sleep/wake cycle disturbance Score 1 point for:**

- A. Sleeping less than 4 h at night OR
- B. Waking frequently at night (do not include wakefulness initiated by medical staff or loud environment) OR
- C. Sleep ≥4 h during day based on primary caregiver assessment

8. **Symptom fluctuation Score 1 point for:**

Fluctuation of any of the above items (i.e., 1–7) over 24 h (e.g., from one shift to another) **based on primary caregiver assessment**

TOTAL ICSDC SCORE (Add 1–8)

This 8-item checklist should be completed using clinical information gathered over the last 8 or 24 h. First assess level of consciousness. If level of consciousness is C, D, or E proceed with the remaining items. Patients are given 1 point for having an obvious manifestation of the item. A score of 4 or greater is considered a positive delirium screen.

SAS, Riker Sedation-Agitation Scale; LOC, level of consciousness.

haloperidol or placebo, there was no difference in the incidence of delirium or the number of days alive without delirium.[122] A second smaller study of 68 patients with subsyndromal delirium (i.e. delirium symptoms that do not meet the full diagnostic criteria for delirium) who were randomized to haloperidol or placebo found no significant differences in the number of patients who subsequently developed delirium.[123] The findings of these trials are supported by a meta-analysis.[124] In contrast to these negative studies of antipsychotics, nocturnal (i.e., given between 9:30 P.M. and 6:00 A.M.) dexmedetomidine was found to reduce the risk of developing delirium. Among 100 mechanically ventilated patients who were receiving sedation and who were not delirious, those who were randomized to receive dexmedetomidine had a 44% greater chance of never developing delirium.[125]

■ Treating Delirium

After implementing the preventative measures, practitioners will likely continue to observe delirium in the ICU. Because delirium often serves as the "canary in the coal mine," heralding the onset of a new or exacerbated underlying pathology (e.g., infection, shock, metabolic abnormality) or a response to a deliriogenic medication, a positive screen for delirium should prompt an immediate search for, and correction of, an underlying etiology and any modifiable risk factors. After addressing potentially modifiable causes of delirium, pharmacologic therapies can be considered.

For many years, antipsychotics were the mainstay of treatment for delirium in the ICU.[126] Data from two placebo-controlled trials, however, suggest that these drugs have no effect on delirium. In a single-center trial, Page et al. randomized 142 mechanically ventilated patients to receive either haloperidol or placebo for up to 14 days.[127] There were no differences between groups in the number of days alive with normal brain function (i.e., the number of delirium/coma-free days) between groups. Patients randomized to treatment with haloperidol had less overall agitation (less time spent at a RASS +2 or more agitated), suggesting that this agent could serve as a sedative-sparing agent even though it did not alter the duration of delirium. A second trial, which was much larger and recruited patients in multiple hospitals throughout the United States, compared treatment of delirium with haloperidol versus ziprasidone versus placebo in 566 patients being treated for respiratory failure or shock.[128] The primary outcome—the number of days alive without delirium or coma during the 14-day study period—did not differ between groups. Likewise, there were no significant differences between groups in duration of hypoactive or hyperactive delirium or in 30- or 90-day mortality. Combined, these trials provide strong evidence that neither haloperidol nor ziprasidone should be used to treat delirium during critical illness. Based on these data, clinical practice guidelines recommend against the use of antipsychotics for the treatment of delirium.[5]

Given the recent data suggesting that pharmacologic therapy is ineffective for the treatment of delirium, the clinician may wonder how to reduce the burdens of this syndrome. Emerging data suggest that an evidence-based multicomponent strategy known as the “ABCDEF” bundle is effective in reducing both the presence and duration of delirium in the ICU. Components of the bundle include Assessment, prevention, and management of pain; Both spontaneous awakening and breathing trials: careful Choice of analgesia and sedation; Delirium assessment, prevention, and management; Early mobility and exercise; and Family engagement/empowerment.

Implementation of this strategy has been shown to be effective in reducing delirium and improving other clinical outcomes across individual hospitals, health systems, and a multicenter collaborative that included community, federal, and academic centers across the United States. Balas et al. compared outcomes before and after bundle implementation.[129] Following implementation, the proportion of patients who ever developed delirium was reduced by 13%, and the proportion of days patients spent in the ICU with delirium was reduced from 50% to 33%. Building on these findings, Barnes-Daly et al. implemented the bundle across ICUs at 7 community hospitals in Northern California over the course of a year.[130] In more than 6000 patients, increasing bundle performance (both in the number of days and amount of bundle elements performed) was associated with a significant increase in the number of days alive and without delirium

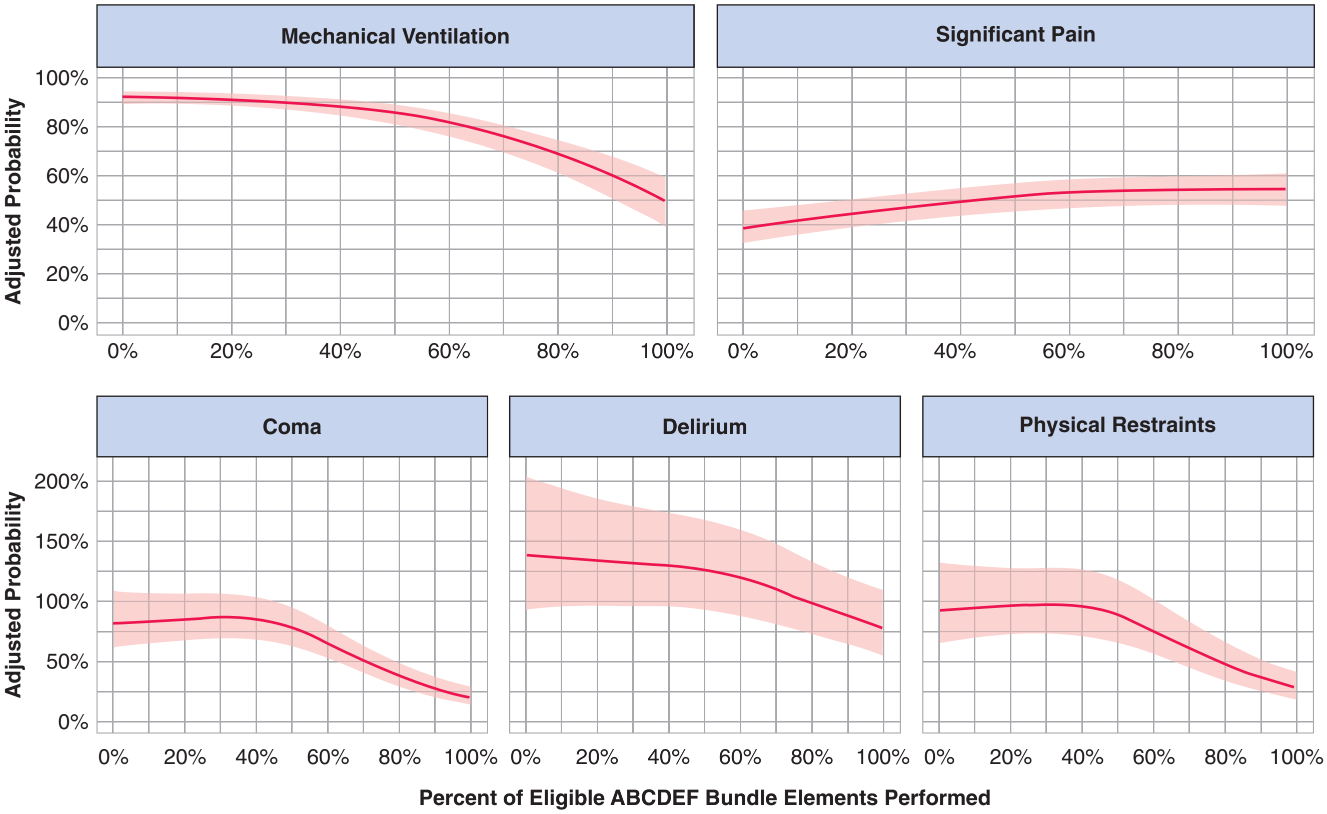

Figure 151-5 Clinical Outcomes associated with the ABCDEF Bundle. These figures show the relationship between the proportion of ABCDEF bundle elements performed *(x-axis)* and the adjusted probability of the clinical outcome the following day *(y-axis)*. The *solid lines* represent the association, and *shading* represents the 95% confidence interval. The top left panel shows a reduction in the probably of being treated with mechanical ventilation. The top right panel shows an increase in patient-reported pain. The bottom left panel shows lower probability of being comatose, the bottom center panel shows a lower probability of being delirious, and the bottom right panel shows a lower probability of being treated with physical restraints. *(Reproduced with permission from Pun BT, Balas MC, Barnes-Daly MA, et al. Caring for Critically Ill Patients with the ABCDEF Bundle: Results of the ICU Liberation Collaborative in Over 15,000 Adults, Crit Care Med. 2019;47(1):3–14.)*

or coma. Furthermore, more days of bundle performance and more elements performed were associated with greater hospital survival.

A large multicenter collaborative implemented the ABCDEF bundle in more than 68 centers across the United States during a 20-month cohort study.[131] Among more than 15,000 patients with at least 1 full day in the ICU, implementation of the bundle was associated with improved clinical outcomes such that as more of the bundle elements were performed, the chances of a patient having delirium the following day were reduced (Fig. 151-5). Similar dose-dependent relationships were seen between greater bundle performance and improved clinical outcomes such as a lower probability of being treated with mechanical ventilation, being comatose, and being treated with physical restraints. The only clinical outcome that worsened with implementation of the ABCDEF bundle was an increase in patient-reported pain, likely because patients were more alert and therefore able to communicate pain.

CHAPTER 152

Ethics and Palliative Care in Critical Care Units

Joshua B. Kayser

Horace M. DeLisser

INTRODUCTION

Death is common in the intensive care unit (ICU), with approximately 20% of deaths in the United States occurring during or shortly after a stay in an ICU.[1] Many of these deaths involve the withholding or withdrawal of life-sustaining therapy, with considerable site variability.[2,3] Therefore, the ICU represents a particularly distinct clinical setting where the thoughtful and considered application of ethical concepts is required. A proper understanding of the basic principles of bioethics as well as the principles of providing comfort-focused, end-of-life care are essential elements in the competent practice of intensive care medicine.

A number of common ethical themes arise in the ICU. Technologic advancements have allowed healthcare providers to keep patients alive for prolonged periods in the context of diseases that, in the past, would have resulted in death. However, the capacity for delivering life-sustaining care has not been completely matched by efforts to align treatments with the care individual patients wish to receive at end of life, resulting in a potential discordance between care wanted and care received.[4–6] Compounding this problem is the reality that many patients dying in the ICU, prior to death, lack the capacity to make decisions regarding end-of-life care[7] and have not completed an advance directive that might aid surrogates and physicians in the decision-making process.[8] Many decisions about end-of-life care in the ICU are, therefore, made without the involvement or input of the patient.[7] The resulting uncertainty means that many patients frequently receive far more aggressive interventions than they would have otherwise chosen for themselves, or they receive care that has a low likelihood of restoring health, enabling discharge from the ICU, and having the potential for providing a meaningful quality of life.[6]

Ethical dilemmas that characterize critical care medicine often arise from this interface between the ability to prolong life by expensive and sometimes scarce technology and an inability to cure patients or restore them to their baseline. The relevant ethical question often is whether technology is being used wisely—that is, should the patient's life be prolonged? The question becomes even more complex for practitioners and patients' families when different ethical principles suggest conflicting answers.

Although the practice of critical care medicine encompasses a broad range of bioethical issues, several are particularly common, including palliative and end-of-life care, surrogate decision-making, medical futility, communication, and professionalism. These issues are among the most challenging for critical care practitioners and constitute the focus of this chapter.

FUNDAMENTAL PRINCIPLES OF BIOETHICS

Several fundamental principles of bioethics are at the core of the practice of critical care medicine: respect for patient autonomy, beneficence, nonmaleficence, and distributive justice.[9] Ethical dilemmas in the ICU arise when two or more of the principles are in conflict. An understanding of these areas provides a basis for addressing conflict and is imperative in providing high-quality palliative care at the end of life.

Respect for Patient Autonomy

The principle of patient *autonomy* refers to the concept of self-determination, which asserts that a competent and informed adult patient possessing adequate decision-making capacity has the right to determine what will be done to his or her body.[9] According to this principle, the patient has the ethical right to accept or refuse medical interventions, including those that might sustain life. In addition, the principle of autonomy encompasses the right to privacy and the requirement for informed consent. As such, except in an emergency, a competent adult must give informed consent before receiving medical care, especially interventions that have the potential to cause further harm or death. Under emergency conditions, consent is presumed. Respect for patient autonomy is applicable with respect not only to patients, but also to their families and surrogate decision makers or proxies—that is, individuals who speak on behalf of patients who lack the capacity to make medical care decisions.

In the United States, societal and professional consensus, as well as statutory law and judicial precedents, support the principle of patient autonomy. Absent countervailing obligations, healthcare providers are required to respect a competent and informed patient's decision to forgo life-sustaining care. Important to note, however, is that autonomy does not provide patients or their surrogates with the right to demand and receive any desired treatment. Rather, patients or their surrogates are permitted to accept or forgo medical interventions that fall within the standard of medical care.

Beneficence and Nonmaleficence

The principle of *beneficence* obligates healthcare providers to promote the well-being of their patient and provide services that benefit the patient.[9] *Nonmaleficence* is the duty to minimize pain and suffering.[9] The Hippocratic maxim *primum non nocere,* which can be translated as "first, do no harm," reflects the fundamental importance of this principle for physicians. Both principles relate to the provision of care that maximizes each individual's dignity and worth as a human being. However, a constant tension exists between these two principles: efforts to cure medical illness often come with substantial suffering. Provided the benefits outweigh the harms, administration of life-sustaining therapies is appropriate. However, once the physician believes the attendant harms may be greater than the foreseen benefits, the physician is obligated to communicate his or her concerns to patients and/or their families. A common example of this tension is provision of cardiopulmonary resuscitation (CPR) to patients who have refractory sepsis despite aggressive medical intervention. The medical literature indicates that offering CPR in this setting is unlikely to restore spontaneous circulation, or at the very best, delay the dying process.[10,11] Consequently, offering CPR in this context could constitute a harm that outweighs the benefits. Despite this ethical construct, the proportion of patients receiving CPR prior to death continues to rise, particularly among minority groups.[10]

Distributive Justice

Justice refers to fairness in the distribution of limited resources, that is, *distributive justice*.[9] Ethically, this principle holds that equals should be treated equally, and unequals treated unequally. In practice, the principle of distributive justice pertains to defining fairness in allocating resources among individuals when not all can receive the resources. The principle is applicable on two levels in health care: macroallocation and microallocation of resources.

Macroallocation entails the distribution of resources among various goods and services at a governmental or institutional level. In contrast, *microallocation* refers to decision-making about an individual patient or small group of patients within, for example, an individual ICU or hospital. A single formulation for the application of this principle in patient care is not available because widely accepted criteria are lacking. Various ethical theories (e.g., deontology, utilitarianism, egalitarianism, among others) define different values as the most relevant criteria for making such judgments. In general, determinations of how to allocate resources and treat patients are best left to institutional or governmental authorities, while physicians provide reasonable and appropriate care on an individual patient basis. Issues of distributive justice have been the subject of significant attention during the recent COVID-19 pandemic.[12]

CONSIDERATIONS IN END-OF-LIFE CARE IN THE ICU

A number of considerations constitute the core practice of bioethics in the ICU. Included are the withdrawal and withholding of life-sustaining therapies, surrogate decision-making, trust and communication, provision of good palliative care, and medical futility. In this regard, bioethics in the ICU should not be viewed as a fixed body of knowledge, but rather as a continually evolving field, similar to the rest of clinical medicine.

Withdrawal and Withholding of Life-sustaining Therapy

Over the last several decades, a broad societal consensus has developed in addressing the ethics of withholding or withdrawing life-sustaining therapies or "life support." Landmark judicial cases, such as the 1976 New Jersey Supreme Court decision regarding Karen Ann Quinlan[13] and the 1990 U.S. Supreme Court decision regarding Nancy Cruzan,[14] played substantial roles in defining both ethical and legal standards. Based on the principle of autonomy, the current societal and legal standard is that adequately informed adults possessing decision-making capacity have the right to refuse any life-sustaining medical therapy, even if the decision results in death. *Capacity* requires that the patient have the ability to comprehend relevant information, understand their condition, compare and contrast treatment options, and communicate wishes consistently.[15]

In practice, no meaningful legal or ethical difference exists between withdrawing and withholding life-sustaining therapy. In addition, legal precedent has established that artificial nutrition and hydration are considered medical interventions that are no different than CPR or mechanical ventilation. The legal issue of whether artificial nutrition and hydration provided by a feeding tube constitutes medical care was decided when the U.S. Supreme Court deemed it so in its 1990 decision on Nancy Cruzan.[14] This decision established a constitutionally protected legal right to refuse any medical care by a competent adult or appropriate surrogate decision-maker acting in accord with the patient's previously expressed preferences or values, including artificial nutrition and hydration. Of note, despite the legal and moral equivalence between withdrawal and withholding of life-sustaining therapy, many patients, families, and healthcare providers often perceive differences between the two.

Morally, controversy continues to exist over the distinction between actions and omissions leading to a patient's death.[16,17] Although the debate is ongoing in the United States, currently, withdrawal and withholding of life-sustaining therapies (sometimes referred to as passive euthanasia) are permissible. In contrast, active euthanasia, where a physician administers an intervention with the intent of hastening death, is neither morally nor legally permissible. This is in direct contradiction to attitudes in many other countries, including parts of Western Europe, where active euthanasia is currently practiced.[18]

Relief of Pain and Suffering

A key ethical principle in end-of-life care is that physicians are obligated, whenever possible, to provide relief of pain and suffering and ensure a dignified death for the dying patient. *Dignity* can be defined in various ways, but at its core is the idea that patients should be treated respectfully and humanely. This includes efforts to keep the patient clean and comfortable, with as little distress as possible. Control of pain is particularly important in the ICU, where significant doses of sedatives may be required to relieve suffering. For some healthcare providers, fear exists that administration of high doses of sedating medications could suppress respiration or cause hemodynamic instability, thus accelerating the dying process. Consequently, they may underdose patients to prevent potential side effects. Unfortunately, this approach carries the unintended consequence of incompletely or ineffectively controlling pain and suffering, thereby diminishing the quality of the dying experience for both the patient and their loved ones.

The *doctrine of double effect* is a key ethical principle that guides the practice of end-of-life care and informs our understanding of how we can effectively relieve pain and suffering. It holds that if, in the process of treating pain or distress of a dying patient, an intervention has the unintended consequence of hastening death, it is ethically and morally permissible.[9] In other words, as long as the intent is not to hasten death, aggressive treatment of symptoms to achieve comfort for the dying patient is acceptable and encouraged and is consistent with the ethical principle of beneficence. This should not be confused with active euthanasia or assisted suicide. The intention of active euthanasia or physician-assisted suicide is specifically to *cause* the patient's death. Based on current societal norms and judicial precedent, active euthanasia is ethically and legally distinct from withdrawal and withholding of life-sustaining therapies, which are intended to allow patients to die from their underlying disease.

Surrogate Decision-making

As noted previously, a majority of patients in the ICU lack the capacity to provide either informed consent for, or refusal of, a medical intervention.[7] Many factors may compromise decision-making capacity, including pain, anxiety, disorientation, fear, sleep deprivation, effects of the underlying disease, and the use of sedatives and narcotics. Unfortunately, most patients have not previously discussed their wishes with family and friends or outpatient medical providers, and they often have not completed an advance directive to articulate their wishes.[8]

When patients lack adequate decision-making capacity, surrogate decision makers are often involved in decisions to limit life-sustaining therapy. The current approach for decision-making in the ICU is a shared decision-making model, in which providers offer information about medical issues, anticipated benefits, and the patient's prognosis, while families provide an understanding of the patient's values and preferences.[19–21] Some patients may have previously explicitly identified a surrogate decision-maker. In the absence of an identified individual, standards for identifying someone to fill that role vary from state to state.

Under ideal circumstances, the surrogate is an individual who knows the patient well and has a good understanding of the patient's values and preferences, allowing them to advocate for the patient based on the *substituted judgment standard*. This standard holds that the surrogate must have knowledge about the patient's wishes, as expressed orally or in writing, or about the patient's values and life goals, from which valid inferences can be made. In situations in which the patient's explicit wishes are unknown, the healthcare team and the patient's loved ones should work collaboratively to make decisions based on the *best interest standard*, taking into consideration the patient's values, preferences, life goals, prior medical decisions, current condition, and prognosis. Under this standard, the surrogate, along with the caregivers, must base their decision on a weighing of the benefits and burdens of life-sustaining therapy—for example, the benefits of life, chance of survival, and chance of full recovery with a high quality of life, compared with the burdens of pain, additional suffering, and poor quality of life.

For a small subset of patients, a surrogate decision-maker cannot be identified.[22] Uniform standards for managing patients in this situation are lacking. In general, the manner in which this circumstance is handled varies by institution and may include multiple physician opinions, chief medical officer concurrence, and/or hospital ethics committee review. Institutions are encouraged to establish a written policy for this practice. Recently, some guidance has been issued to better standardize care for unrepresented patients.[23]

■ Medical Futility

An example of when ethical principles may conflict is in the ongoing debate over the use of medical futility to guide care of critically ill patients. While there are various conceptions of futility in health care, broadly, an intervention may be considered *futile* when it is incapable of accomplishing the result for which it is intended.[24] In the ICU, this goal is typically understood to be meaningful recovery from critical illness, where *meaningful* refers to a survival that the patient can value and appreciate.

An important distinction exists between *physiologic futility* and *medical futility*. An intervention that is judged to be *physiologically futile* is one that is not expected to, or does not achieve, the relevant physiologic function as an endpoint. There is both an ethical and professional consensus that healthcare providers are not required to provide such interventions.[25] As described previously, CPR may be judged to be physiologically futile in a patient with refractory septic shock complicated by cardiac arrest after progressively worsening hypotension, despite maximal therapy. Under these circumstances, the conclusion that CPR would have extremely little or no chance of success (beyond, possibly, a brief time period) is well supported by published literature and clinical experience. Further, an attempt at CPR would not only prolong the patient's dying but could also do physical harm by fracturing ribs and burning the skin. Prolonging dying is not one of the goals of medicine, and under these circumstances, CPR would violate the principle of nonmaleficence. Moreover, an argument has been made that forcing healthcare providers to perform CPR when there is virtually no prospect of success undermines the ethical integrity of the medical profession.[25]

Medical futility is more difficult to define than physiologic futility and is, therefore, less well supported in its application. Some of the older literature describes qualitative approaches, in which experience suggests an intervention will not result in a meaningful survival,[26] as well as quantitative approaches, in which the success of interventions is measured in a more standardized way.[27] However, it is important to recognize that physicians may be limited in their ability to accurately determine the prognosis of a patient.[28] Furthermore, what constitutes meaningful survival or good quality of life is inherently unique to a particular individual and, therefore, is difficult to measure. Consequently, employing a medical futility standard, rather than a physiologic standard, is more challenging. In recent years, professional societies have developed and recommended standards for responding to requests by patients and surrogates for potentially inappropriate treatments in the ICU. This includes avoidance of term "futile" to address interventions that are not physiologically futile but for which there is a competing ethical rationale not to offer the intervention. Included in these standards is a strong recommendation not to offer physiologically futile interventions.[24]

Not uncommonly, patients or their families request continuation of treatments that physicians believe are incapable of producing meaningful survival, based on the principle of autonomy. This tension between the rights of patients as autonomous beings and the obligation of physicians to honor the principles of beneficence and nonmaleficence may result in conflict between the parties. In this setting, the current ethical norm is that potentially inappropriate treatments should not be unilaterally withheld to circumvent patient or surrogate wishes when conflict exists with regard to the value of an intervention. Specifically, in the absence of predetermined, institutionally based criteria, individual physicians should not attempt to unilaterally withhold or withdraw life-sustaining therapies against the wishes of patients and surrogates on this basis. Instead, if a physiologic futility standard is to be used, it should be applied based on an explicitly defined institutional policy that is transparent, is inclusive of patients and their families, ensures effective communication, and incorporates an appeal process. Ultimately, conflict that is mediated by parties to achieve a mutually agreeable solution is preferable to invoking "futility."[24]

■ Communication and Professionalism

As noted previously, disagreements regarding the plans and goals of care arise at times between medical providers and patients or their surrogates. Frequently, disagreements are a consequence of a breakdown in communication or a loss of trust by the patient or the patient's surrogate for the medical team.

Recognizing the value of good communication and trust in the ICU serves to enhance the quality of care, promote the autonomy of the patient, and increase the likelihood of a patient-centered outcome. Rather than being assumed, trust should be viewed as something that must be earned from each patient and their family. Trust can be earned by providing compassionate care, communicating with patients and their families on a regular basis, encouraging dialogue, and listening empathically.

Good communication starts with a determination to uniquely understand each patient and to engage patients and families in a culturally sensitive and transparent manner. Information should be presented in a language, and at a level of detail, such that patients and their surrogates feel well informed. This is particularly important in light of studies that have found that a large proportion of patients and surrogates are unable to clearly express an understanding of medical facts, diagnoses, and prognosis after meeting with physicians[29] and that many surrogates are overly optimistic about their loved ones' predicted outcomes.[30] In addition, the proportion of time families are allowed to speak during family meetings correlates with the degree of their satisfaction with the care.[31] Despite these data, studies have shown that physicians typically do the majority of the talking and rarely initiate discussions about values and goals.[32,33]

The timing and manner of discussions with patients and families may vary, ranging from informal discussions on daily rounds to more formal family meetings to discuss changes in the goals of care. Efforts should be made to engage families initially at the time of admission, followed by a more formal discussion after 24 to 48 h to review events related to ICU care. This meeting should be less about goals of care or prognosis, and more about providing support for the family, while describing expectations for recovery and establishing benchmarks for recovery or decline. Following the meeting, short daily debriefings should occur to provide updates on the clinical status of the patient and the care being provided. If the patient declines clinically and it becomes clear that chances of recovery are limited, honest and open discussions should occur to provide truthful assessments of the patient's prognosis. Transparent communication enhances patient autonomy and allows families to make more informed decisions about the care of their loved one. This does not mean that all medically available options can, or even should, be discussed with each patient and family. The decision to offer specific treatments should be based on the medical judgment that the treatments in question are beneficial to the patient; they should be informed by a clear understanding of the patient's values and known wishes—what some have referred to as *authentic decisions*.[34]

Each family will vary in its comfort with the responsibilities of being surrogate decision-makers and the amount of information needed to make decisions.[35–37] While some families may prefer greater detail and more autonomy to make care decisions, others may lack the ability to process significant amounts of medical information, or they might prefer to take a lesser role in decision-making, deferring to the medical judgment of the physician. Evidence suggests that discordance in decision-making roles may substantially increase the incidence of anxiety and posttraumatic stress disorder (PTSD) among surrogates.[38] Consequently, identifying the category into which each family or members of families fit is essential for successful engagement and provision of adequate support.

Finally, the ICU and critical illness can be potentially overwhelming to patients and families.[39] The ICU experience can evoke powerful emotions, including fear, anger, frustration, guilt, and intense grief—emotions that are as important as physical symptoms and that need to be addressed by clinicians with empathy, patience, and understanding. At times, physicians may need to take time out from direct patient care to actively listen and allow patients and families to express their concerns and discuss the emotional burden of having a loved one in an ICU. These opportunities for empathic discussion provide for not only a catharsis for the patient or family but also a chance for the physician to obtain further insight into the patient's life, goals, and wishes, further enhancing trust. In addition, offering opportunities for family members to be involved in participating in the care of their loved one at high risk for dying in the ICU may reduce symptoms of posttraumatic stress disorder in family members.[40]

Discussing Goals of Care for the Dying Patient

Many patients fail to improve and will die in the ICU. As such, end-of-life discussions have a prominent role in the management of critically ill patients. One of the most difficult and important roles of the ICU physician is to engage in end-of-life discussions with patients and surrogates when it becomes evident the patient will not survive. Included in these discussions are efforts to reach consensus regarding the goals, and the subsequent plan, of care. Agreement is most likely to be reached when trust has been established through good communication. Although each circumstance is unique, basic communication skills and techniques can enhance the quality and success of these meetings.

Critical to the success of these discussions is advance preparation by the medical team, development of a clear understanding of the facts at hand, and establishment of a consensus regarding the best course of action before meeting with the family. Consideration of which team members should be present at the meeting is necessary to facilitate a patient-centered discussion and to reduce the likelihood of overwhelming the family. Ideally, the medical team members should not outnumber the family. At a minimum, the primary ICU physician and bedside nurse should be present. Other participants might include staff from pastoral care, social work, palliative care services, and, when appropriate, the patient's outpatient primary provider. Family members should be made aware of the purpose of the meeting in advance and should be offered the opportunity to meet at a time and place that allows for as many members as appropriate to participate. Determining the size or number of family members should be based on each unique case, but the meeting should incorporate essential members, including those directly involved in decision-making. Table 152-1 outlines recommendations for facilitating the goals of care meeting. While these recommendations are not proscriptive, they summarize the current published literature on the best practice for approaching these discussions.[19,34,41,42]

TABLE 152-1 A Recommended Approach for Facilitating the Goals of Care Meeting

- I. Preparation phase
  - (i) Notify family and friends of the time and location of the meeting
  - (ii) Hold a premeeting huddle
    - a) Confirm understanding of medical facts, prognosis, and direction of care and ensure team agreement about proposed changes to the goals and plan
    - b) Consider who should be present at the meeting and how to approach potential issues that may arise during conversation
  - (iii) Establish conditions for a productive conversation
    - a) Designate a quiet space for the meeting
    - b) Silence pagers and phones
    - c) Provide boxes of tissue
    - d) Disperse team members throughout the room
- II. Discussion phase
  - (i) Describe the purpose and goal of the meeting
  - (ii) Have everyone introduce themselves and state their relationship to the patient
  - (iii) Express appreciation for everyone's willingness to participate in the meeting
  - (iv) Determine and clarify the family's understanding of medical facts
  - (v) Provide additional information about anticipated prognosis and trajectory
  - (vi) Elicit fears, concerns, expectations, hopes, etc. from family and friends
  - (vii) Ask about the patient's life, values, and goals
- III. Negotiation phase
  - (i) Recommend treatments and options consistent with the patient's goals
  - (ii) Develop explicit consensus about the plan of care
  - (iii) Ensure all voices have been heard
- IV. Debriefing phase
  - (i) Summarize agreed upon plan of care
  - (ii) Describe next steps for patient care
  - (iii) Respond to unanswered questions
  - (iv) Attend to emotions
  - (v) Invite the family to share personal stories or experiences about the patient
  - (vi) If appropriate, invite prayer by a family member, their clergy, or a hospital chaplain
  - (vii) Acknowledge the difficulty of the conversation and decisions made
  - (viii) Assure ongoing care for the patient
  - (ix) Thank the family for their involvement

The goals of care meeting can be divided into four phases: preparation, discussion, negotiation, and debriefing. The preparation phase is a premeeting opportunity for the medical team to assemble and agree on what will be discussed, as described previously. The discussion phase is the early portion of the meeting, during which the medical team has an opportunity to describe current medical facts and prognosis, and the family has an opportunity to express fears, concerns, and expectations. The negotiation phase is an opportunity for the entire group to develop a mutually agreeable plan of care and to establish boundaries and limitations on care based on the patient's values, the family's individual hopes and wishes, and the medical realities of the patient's condition. Finally, the debriefing phase allows the medical team to provide emotional support to the family and to come together after the meeting to prepare to implement the agreed-upon plan of care.

Providing Palliative and End-of-life Care in the ICU

Palliative care is an essential component of good patient care in the ICU and has been strongly advocated as a core competency at an international level.[43] Good palliative care matches the care patients desire at end of life with that which they receive and can increase quality of life for patients prior to death. In addition, palliative care can enhance the perception of quality of death among family members and reduce instances of complicated bereavement, including caregiver depression, anxiety, and PTSD.[4] The vast majority of deaths in the ICU are preceded by a change in goals of care toward an approach that emphasizes comfort over cure. As such, a strong foundation and comfort with principles of hospice and palliative medicine is essential to the comprehensive care of critically ill patients. In addition, standardized policies are critical to ensuring effective and efficient relief of pain and suffering in the terminally ill.

The fundamental goal of palliative care is to restore or maintain quality of life and prevent needless physical or emotional suffering for patients and their loved ones. This includes not only administering analgesics and other medications to relieve symptoms of the dying process, but also providing other compassionate care. In fact, it is important to explicitly state that while palliative care encompasses limiting or discontinuing various life-sustaining interventions, it does not mean we are limiting "care" for our patients and their loved ones. In addition to symptom control, "care" also means providing general patient hygiene and attending to the spiritual, emotional, and psychological distress of the patient and the family of a dying patient. As an example of a simple, yet successful, intervention, use of empathic statements about the difficulty of making decisions to withhold or withdraw life-sustaining therapy and losing a loved one have been associated with increased ratings of family satisfaction and bereavement among surrogates.[44]

Once the decision is made to focus exclusively on care that promotes comfort, only treatments and interventions that achieve this goal should be employed. As appropriate, opiates and sedatives should be titrated to prevent pain, dyspnea, or anxiety before withdrawing life-sustaining therapies. When the patient is perceived to be comfortable by the medical staff and family, all life-sustaining interventions should be withdrawn or withheld so as to not prolong the dying process. While care should be tailored to the wishes and values of each family, some basic guidelines should be followed.

First, a clear explanation should be provided to the patient's loved ones before initiating comfort care interventions. Families should understand that comfort care will be provided throughout the dying process, and that time to death is variable. In addition, family should be offered the opportunity to be present at the time of death, understanding that for some, presence is associated with increased incidence of PTSD.[45] Second, withdrawal of all agreed-upon life-sustaining therapies should occur at one time, rather than in a sequential fashion, to minimize discomfort to the patient and disruption to the family. Third, any evidence of recurring pain, anxiety, or discomfort, as witnessed by a team member or family, should be aggressively treated. This includes any spiritual or existential suffering, which should be addressed with the support of palliative and pastoral care services. Fourth, when possible, in-room physiologic monitoring should be discontinued, as well as unnecessary medications, tests, devices, vascular access, and catheters. Finally, members of the medical team should be in close proximity and readily available to quickly address any issues that arise.

As a general rule, actively dying patients should not be transferred out of the ICU unless the bed is needed for a new critically ill patient. These patients often require high levels of nursing and physician support and typically die relatively quickly after life-sustaining therapies are withdrawn. In addition, leaving the patient in the ICU allows for continuity of care, which can be immensely helpful to grieving families. However, for patients whose needs for palliative care can be met by a less intense level of nursing and medical care, or for patients whose death may not be imminent, consideration should be given to transferring that patient to another room outside of the ICU, where there is more privacy and quiet during the dying process. Some hospitals have hospice units with specially trained nursing and medical staff and pleasant, private surroundings for patients and families. It is customary for hospital visiting hours to be suspended for dying patients.

CONFLICT RESOLUTION IN THE ICU

As a rule, good communication and sustaining of trust in the ICU significantly lessen the likelihood of conflict between healthcare staff and patients and their families. Unfortunately, conflict does arise at times. Although some disagreements may be based on ethical issues (e.g., autonomy vs. beneficence), in most instances conflict occurs due to breakdowns in communication, a loss of trust, or both. At these moments of conflict, it is important to recognize that individuals each have their own sets of values and beliefs that may inform their opinion about a plan of care. This applies not only to patients and their families, but also to medical staff as well. In addition, the ICU is a challenging environment. ICU staff are busy, patient conditions rapidly change, and families suffer from varying degrees of emotional distress. Recognizing and acknowledging these challenges is important in achieving resolution of conflict.

Conflict resolution begins with open communication among all parties. Usually, patient and honest negotiation between parties will result in resolution. In particular, attempting to understand the values and perspective of patients and their families can improve the communication process and diffuse difficult situations. However, at times further discussion may not resolve the dispute. At that point, a number of additional strategies may be considered.

Palliative Care Consultation

Palliative care services are an excellent resource for providing additional support in the end-of-life process. In addition to expertise in symptom control, palliative care teams can provide supportive counseling to patients and families, improve communication with the medical team, and aid in conflict resolution. Various studies of the effectiveness of palliative care consultation in the ICU suggest the potential for improved quality of death and dying, increased advance directive completion rates and hospice discharge rates, reductions in utilization of nonbeneficial life-sustaining therapies, and reductions in hospital and ICU length of stay.[46,47] In the absence of dedicated palliative care consultative services, social work and pastoral care (two common members of the palliative care multidisciplinary team) may be able to provide support.

Ethics Consultation and Bioethics Mediation

Another potential option for dealing with conflict resolution is the hospital ethics committee. Ethics consultants are excellent resources for clarifying ethical uncertainty when it arises. However, much of the conflict occurring in the ICU is not truly of an ethical nature. In this context, ethics consultation may not necessarily be helpful. In general, use of ethics consultation has produced similar outcomes as the palliative care interventions described earlier.[48]

When not employed appropriately, ethics consults may be viewed as arbitrary and biased in favor of the hospital and medical team. Rendering a decision runs the risk of not meeting the needs of the patient and family and increasing conflict. Given these reservations, it is imperative that hospital ethics committees have sufficient community representation and seek out the involved patients and their families directly to enable a complete understanding of their values, perceptions, and goals when conflict exists.

More recently, bioethics mediation has emerged as another potential approach for resolving conflicts in the ICU. Mediation has been practiced in legal and business settings for decades. Although new to health care, mediation offers an alternative means of handling disputes by focusing on a shared decision-making model, rather than the win–lose scenario of the healthcare team versus the patient and family.

Mediation operates under the premise that mutually agreeable solutions can be negotiated when conflict arises between multiple parties involved in the care of a patient. Unlike legal and business settings, healthcare mediation is nonbinding and, therefore, might be more akin to marriage counseling than true legal mediation. In this sense, it is perhaps better termed "facilitation." The goal of mediation is to create a neutral environment for all parties to come together and share perspectives and concerns. Although promising, bioethics mediation in the healthcare setting remains untested. Furthermore, there are few individuals currently trained in bioethics mediation to make its practice widely applicable at this time. There is, however, a growing sentiment that ICU clinicians should have some knowledge or training in principles of mediation to effectively negotiate conflict.[49,50]

■ Strategies When Conflicts Persist

Even with the previously noted resources, times will arise when the relationship between providers and patient or family is irrevocably damaged, and further communication and negotiation will not successfully resolve the conflict. In these settings, healthcare providers may find themselves providing care they believe to be ineffective or even harmful. This can have unfortunate consequences of burnout and cynicism, both of which can result in erosion of professionalism and poor quality of care for current and future patients.[51] If a provider feels strongly that he or she cannot, in good conscience, offer the care that the patient or family is requesting, the provider may transfer the care to another provider within the same institution or offer to transfer to another hospital. However, if another provider or hospital cannot be identified, it is vital that the medical staff support each other while continuing to provide good care to their patients. One effective approach that is being adopted in many ICUs to minimize emotional and moral distress is "death" or "grief" rounds, during which ICU staff come together to debrief and discuss difficult cases. Grief rounds allow staff to decompress and avoid burnout that could otherwise negatively impact job satisfaction and patient interaction.[52]

CONCLUSION

In today's critical care environment, death in the ICU is common and usually occurs after life-sustaining therapy is withheld or withdrawn. Many ethical considerations arise from the frequency and complexity of this process. Consequently, healthcare providers face challenging ethical dilemmas in weighing these considerations while providing care for their patients.

There is broad legal, ethical, societal, and professional support for limiting life-sustaining therapy at the end of life. As a general rule, the overriding principle is respect for patient autonomy. However, physicians must engage patients and their families to create a shared decision-making environment in which medical facts are matched by a desire to understand the values and wishes of patients with critical illness and terminal disease. Ultimately, effective communication enhances the quality of patient care and family satisfaction and is likely to result in patients getting the care they wish to receive.

Conflicts occur, although they can usually be resolved by good communication and honest, respectful engagement. In situations in which communication strategies fail, additional resources (e.g., palliative care, ethics committees, bioethics mediation) may prove helpful to resolve conflict. Only in very rare cases should providers find themselves in situations where they are morally distressed by the care they are required to provide. In these situations, the conflict can be resolved by transferring the patient to another provider or hospital and by supporting each other while continuing to provide high-quality critical care.

ACKNOWLEDGMENT

The authors would like to thank Paul N. Lanken for his contributions to this chapter in a previous edition.

APPENDIXES

Appendix A Terms and Symbols in Respiratory Physiology A-2

Appendix B Normal Values for a Healthy 20-Year Old Seated Man A-5

APPENDIX A

Terms and Symbols in Respiratory Physiology

GENERAL SYMBOLS

P	Partial pressure in blood or gas P_{O_2} = partial pressure of O_2
$\bar{X}$	A bar over the symbol indicates a mean value. $\bar{P}$ = mean pressure, as distinct from instantaneous pressure
$\dot{X}$	A time derivative (rate) is indicated by a dot above the symbol $\dot{V}_{O_2}$ = oxygen consumption per minute, mL $\dot{V}_{CO_2}$ = CO_2 production per minute, mL
% X	Percent sign preceding a symbol indicates percentage of the predicted normal value
X/Y%	Percent sign following a symbol indicates a ratio function with the ratio expressed as a percentage. Both components of the ratio must be designated FEV_1/FVC, % = 100 × FEV_1/FVC
XA, Xa	A small capital letter or a lower-case letter on the same line following a primary symbol is a qualifier to further define the primary symbol. Alternatively, subscript letters may be used XA = X_A, Xa = X_a Additional qualifiers of the primary symbol may be identified as shown PE_{O_2} = Pressure of CO_2 in the expired air, mm Hg

GAS PHASE SYMBOLS

Primary Symbols

V	Volume of gas
$\dot{V}$	Flow of gas
F	Fractional concentration of a gas

Qualifying Symbols

I	Inspired VI = inspired volume
E	Expired VE = expired volume $\dot{V}$E = expired volume per minute
A	Alveolar VA = alveolar volume $\dot{V}$ = alveolar ventilation per minute
T	Tidal VT = tidal volume
D	Dead space VD = volume of dead space $\dot{V}$D = dead-space ventilation per minute
B	Barometric PB = barometric pressure
STPD	Standard conditions: temperature 0°C, pressure 760 mm Hg, and dry (0 mm Hg water vapor)
BTPS	Body conditions: body temperature and ambient pressure, saturated with water vapor at these conditions
ATPD	Ambient temperature and pressure, dry
ATPS	Ambient temperature and pressure, saturated with water vapor at these conditions
an	Anatomic
p	Physiological
f	Respiratory frequency, per minute
max	Maximum
t	Time

BLOOD PHASE SYMBOLS

Primary Symbols

Q	Volume of blood
$\dot{Q}$	Blood flow $\dot{Q}$ = cardiac output, L/min
C	Concentration in the blood phase C_{O_2} = concentration of oxygen in blood, mL of O_2 per 100 mL of blood
S	Saturation in the blood phase S_{O_2} = Saturation of hemoglobin with O_2, percent

Qualifying Symbols

a	Arterial Ca_{O_2} = concentration of O_2 in arterial blood, mL of O_2 per 100 mL of blood
c	Capillary Cc_{O_2} = concentration of O_2 in capillary blood, mL of O_2 per 100 mL of blood
C′	Pulmonary end-capillary Pc'_{O_2} = partial pressure of O_2 in end-capillary blood, mm Hg
v	Venous Cv_{O_2} = concentration of O_2 in venous blood, mL of O_2 per 100 mL of blood
$\bar{v}$	Mixed venous $C\bar{v}_{O_2}$ = concentration of O_2 in mixed venous blood, mL of O_2 per 100 mL of blood

VENTILATION AND LUNG MECHANICS TESTS AND SYMBOLS

Static Lung Volumes*

RV	Residual volume. Volume of air remaining in the lungs after maximum expiration.
CV	Closing volume. Volume of air expired from the onset of airways closure to residual volume. May be expressed as a fraction of VC: CV/VC,%.
ERV	Expiratory reserve volume. Maximum volume of air expired from the resting end-expiratory level.
V_T	Tidal volume. Volume of air inspired or expired with each breath during quiet breathing. When tidal volume is used in gas-exchange formulations, this symbol is used.
IRV	Inspiratory reserve volume. Maximum volume of air inspired from the end-tidal inspiratory level.

Lung Capacities**

IC	Inspiratory capacity. The sum of IRV and TV.
IVC	Inspiratory vital capacity. Maximum volume of air inspired from the point of maximum expiration, i.e., from RV.
VC	Vital capacity. Maximum volume of air expired from the point of maximum inspiration, i.e., from TLC.
FRC	Functional residual capacity. Sum of RV and ERV. FRC is the volume of air remaining in the lungs at the resting end-expiratory position.
TLC	Total lung capacity. Volume of air in the lungs after maximum inspiration. Also, the sum of all volume compartments of the lungs.
RV/TLC,%	Residual volume to total lung capacity ratio, expressed as a percentage.
CC	Closing capacity. Closing volume plus residual volume, may be expressed as a percentage of TLC: CC/TLC, %.

Forced Respiratory Maneuvers During Spirometry†

FVC	Forced vital capacity. The maximum volume of air forcibly expired from total lung capacity
FIVC	Forced inspiratory vital capacity. Maximum volume of air forcibly inspired starting from residual volume.
FEV*t*	Timed forced expiratory volume. Volume of air expired in a specified time in the course of the forced vital capacity maneuver. FEV_1 = volume of air expired during the first second of the FVC.
FEV*t*/FVC,%	Ratio of timed forced expiratory volume to forced vital capacity, expressed in percentage.
FEF*x*	Forced expiratory flow, related to some portion of the FVC curve. Modifiers refer to the amount of the FVC that has been expired at the time of measurement.
$FEF_{200-1200}$	Forced expiratory flow between 200 and 1200 mL of the FVC (formerly called the maximum expiratory flow rate).
FEF_{25-75}	Forced expiratory flow during middle half of the FVC (formerly called the maximum midexpiratory flow rate or MMEF)
PEF	Peak expiratory flow. Highest value for expiratory flow.
$\dot{V}_{max_x}$	Maximum flow when *x* percent of the FVC has been expired. $\dot{V}_{max\,75}$ = flow (instantaneous) when 75% of the FVC has been expired.
FIF*x*	Forced inspiratory flow. As in the case of the FEF, appropriate modifiers designate the volume at which flow is being measured. Unless otherwise specified, the volume qualifiers indicate the volume inspired from RV at the point of measurement. FIF_{25-75} = forced inspiratory flow during the middle half of the FIVC.
MVV	Maximum voluntary ventilation. Volume of air exhaled during maximum breathing efforts within a specified time period. Formerly called the maximum breathing capacity (MBC) MVV_{60} = MVV at a breathing frequency of 60 per minute.
PImax	Maximum inspiratory pressure. The maximum pressure generated during a maximal inspiratory effort made at RV.
PEmax	Maximum expiratory pressure. The maximum pressure generated during a maximal expiratory effort made at TLC.

Measurements Related to Ventilation

$\dot{V}_E$	Expired volume per minute (BTPS)
$\dot{V}_I$	Inspired volume per minute (BTPS)
$\dot{V}_{CO_2}$	Carbon dioxide production per minute (STPD)
$\dot{V}_{O_2}$	Oxygen consumption per minute (STPD)
R	Respiratory exchange ratio, the ratio of CO_2 output to O_2 intake in the lungs
$\dot{V}_A$	Alveolar ventilation per minute (BTPS)
$\dot{V}_D$	Ventilation per minute of the physiological dead space (BTPS) defined by the equation $\dot{V} = \dot{V}_E \dfrac{Pa_{CO_2} - P_{A_{CO_2}}}{Pa_{CO_2} - P_{I_{CO_2}}}$
V_D	Volume of the physiological dead space, calculated as $\dot{V}_D/f$.
V_D/V_T	Ratio of dead space to tidal volume. The fraction, usually expressed as a percentage, of each breath that does not contribute to CO_2 elimination.

Mechanics of Breathing*

Pressure Terms

Paw	Pressure at any point along the airways
Pao	Pressure at the airway opening
Ppl	Pleural pressure
P_A	Alveolar pressure

---

*Expressed as BTPS.

**Combinations of volumes for practical purposes.

†All values at BTPS.

*All pressures expressed relative to ambient pressure unless otherwise specified.

Pbs	Pressure at the body surface
Pes	Esophageal pressure: used to estimate Ppl
PA–Pbs	Transthoracic pressure
PA–Ppl	Transpulmonary pressure
Ppl–Pbs	Pressure difference across the chest wall
Paw–Ppl	Transbronchial pressure, estimated as difference between airway and pleural pressures.

Flow–Pressure Relationships[†]

R	General symbol for frictional resistance, defined as the ratio of pressure difference to flow.
Raw	Airway resistance, calculated from pressure difference between airway opening (Pa_o) and alveoli (Pa) divided by the airflow, cm H_2O/L/s.
Rl	Total pulmonary resistance, measured by relating flow-dependent transpulmonary pressure to airflow at the mouth.
Rti	Tissue resistance (viscous resistance of lung tissue), calculated as difference between Rl and Raw.
Rus	Resistance of the airways on the upstream (alveolar) side of the point in the airways where intraluminal pressure equals Ppl, i.e., equal pressure point. Measured during a forced expiration.
Rds	Resistance of the airways on the downstream (mouth) side of the point in the airways where intraluminal pressure equals Ppl, i.e., equal pressure point. Measured during a forced expiration.
Gaw	Airway conductance, reciprocal of Raw.
Gaw/Vl	Specific conductance, airway conductance, expressed per liter of lung volume at which Gaw is measured.

Volume–Pressure Relationships

C	General symbol for compliance of the lungs, chest wall, or total respiratory system. Volume change per unit change in applied pressure. For the lungs, the applied pressure is the pressure difference across the lungs, or transpulmonary pressure, Pao–Ppl; for the chest wall, the applied pressure is the transthoracic pressure, Ppl–Pbs; for the entire respiratory system, the applied pressure is Pao–Pbs.
Cl	Lung compliance. Value for the volume change divided by the transpulmonary pressure.
Cw	Chest wall compliance. Value for the volume change divided by the transthoracic pressure.
Cdyn	Dynamic compliance. Value for compliance determined at time of zero gas flow at the mouth during uninterrupted breathing. The respiratory frequency appears as a qualifier. $Cdyn_{40}$ = dynamic compliance at a respiratory frequency of 40 per minute.
Cst	Static compliance, value for compliance determined on the basis of measurements made during a period of zero airflow.
C/Vl	Specific compliance. Compliance divided by the lung volume at which it is determined, usually FRC.

Pst	Static pulmonary pressure at a specified lung volume. PST_{TLC} = static recoil pressure of the lung measured at TLC (maximum recoil pressure)

Diffusing Capacity Tests And Symbols

DL*x*	Diffusing capacity of the lung expressed as volume (STPD) of gas (*x*) uptake per minute per unit alveolar-capillary pressure difference for the gas used. A modifier can be used to designate the technique: DL_{CO}/SB = Single-breath CO diffusing capacity DL_{CO}/SS = Steady-state CO diffusing capacity
DM	Diffusing capacity of the alveolar-capillary membrane (STPD).
θ	Reaction rate coefficient for red blood cells. Determined as the volume of gas (STPD) that will combine per minute with 1 unit volume of blood per unit of gas tension. If the specific gas is not stated, θ is assumed to refer to CO and is a function of existing O_2 tension.
VC	Pulmonary capillary blood volume. This should be QC for consistency with other symbols, but VC is entrenched in the literature. In the equation that follows for 1/DL, VC represents the effective pulmonary capillary blood volume, i.e., capillary blood volume in intimate association with alveolar gas.
1/DL	Total resistance to diffusion, including resistance to diffusion of test gas across the alveolar-capillary membrane, through plasma in the capillary, and across the red blood cell membrane (1/Dm), with the resistance to diffusion within the red blood cell arising from the chemical reaction of the test gas and hemoglobin (1/θVC), according to the formulation $\frac{1}{DL} = \frac{1}{DM} + \frac{1}{\theta VC}$
DL/VA	Diffusing capacity per unit of alveolar volume. DL is expressed STPD, and VA is expressed in liters, BTPS.

BLOOD GAS SYMBOLS

Symbols for these values are readily composed by combining general symbols. Some examples include the following:

Pa_{CO_2}	Arterial CO_2 tension, mm Hg
Sa_{O_2}	Arterial O_2 saturation, percent
CcO_2	Oxygen content of pulmonary end-capillary blood, mL of O_2 per 100 mL of blood
$(A\text{-}a)Po_2$	Alveolar–arterial difference in the partial pressure of O_2, mm Hg
$Ca_{O_2} - C\bar{v}_{O_2}$	O_2 content difference between arterial and mixed venous blood (arteriovenous O_2 difference), mL of O_2 per 100 mL of blood

PULMONARY SHUNT SYMBOLS

$\dot{Q}s$	Flow of blood via shunts. This is usually determined as percent of cardiac output ($\dot{Q}$) while breathing 100% O_2, according to the equation $\frac{\dot{Q}s}{\dot{Q}} = \frac{CcO_2 - Ca_{O_2}}{Ca_{O_2} - C\bar{v}_{O_2}} \times 100$ Where CcO_2 = O_2 content of end-capillary blood CaO_2 = O_2 content of arterial blood $C\bar{v}_{O_2}$ = O_2 content of mixed venous blood

---

[†] Unless otherwise specified, resistance measurements are assumed to be made at FRC.

APPENDIX B

Normal Values for a Healthy 20-Year Old Seated Man

Ventilation (BTPS)

Tidal volume (V_T), L	0.6
Frequency (f), breaths/min	12
Minute ventilation (V_E), L/min	7.2
Respiratory dead space (V_D), mL	150
Alveolar ventilation, V_A, L/min	5.4

Lung Volumes and Capacities (BTPS)

Inspiratory capacity (IC), L	3.0
Expiratory reserve volume (ERV), L	1.9
Vital capacity (VC), L	4.9
Residual volume (RV), L	1.4
Functional residual capacity (FRC), L	3.2
Total lung capacity (TLC), L	6.3
Residual volume/total lung capacity × 100 (RV/TLC), %	22

Mechanics of Breathing

Forced vital capacity (FVC), L	4.9
Forced expiratory volume, first second (FEV_1), L	4.0
Maximum voluntary ventilation (MVV), L/min	170
Forced expiratory volume in 1 s/forced vital capacity × 100 (FEV_1/FVC), %	83
Forced expiratory volume in 3 s/forced vital capacity × 100 (FEV_3/FVC), %	97
Forced expiratory flow during middle half of FVC (FEF_{25-75}), L/s	4.7
Forced inspiratory flow at the middle of forced inspiratory capacity (FIF_{50}), L/s	5.0
Static compliance of the lungs (Cst, l), L/cm H_2O	0.2
Compliance of lungs and thoracic cage (CRS, respiratory system compliance) L/cm H_2O	0.1
Airway resistance at FRC (Raw), cm H_2O/L/s	1.5
Pulmonary resistance at FRC, cm H_2O/L/s	2.0
Airway conductance at FRC (G_{aw}), L/s/cm H_2O	0.66
Specific conductance (G_{aw}/V_1)	0.22
Maximum inspiratory pressure, mm Hg	– 75
Maximum expiratory pressure, mm Hg	120

Distribution of Inspired Gas

Single-breath N_2 test (ΔN_2 from 750 to 1250 mL in expired gas), % N_2	<1.5
Alveolar N_2 after 7 min of breathing O_2, % N_2	<2.5
Closing volume (CV), mL	400
CV/VC × 100, %	8
Closing capacity (CC), mL	1900
CC/TLC × 100,%	30
Slope of phase III in single-breath N_2 test, % N_2/L	<2

Gas Exchange

O_2 consumption at rest (STPD), mL/min	240
CO_2 output at rest (STPD), mL/min	192
Respiratory exchange ratio (R), CO_2 output/O_2 uptake	0.8
ALVEOLAR GAS	
PA_{O_2}, mm Hg	105
PA_{CO_2}, mm Hg	40
ARTERIAL BLOOD	
Pa_{O_2}, mm Hg	95
Sa_{O_2}, %	98
pH	7.40
Pa_{CO_2}, mm Hg	40
Pa_{O_2}, while breathing 100% O_2, mm Hg	640

Alveolar Ventilation and Gas Exchange

Alveolar ventilation, L/min	4.2
Physiological dead space/tidal volume × 100 (V_D/V_T), %	<30
Alveolar–arterial oxygen-gradient, (A-a) P_{O_2}, mm Hg	10

Diffusing Capacity

Diffusing capacity at rest for CO, single-breath ($D_{L_{COsb}}$), mL CO/min/mm Hg	29
Diffusing capacity per unit alveolar volume (D_L/V_A)	4.8

Control of Ventilation

Ventilatory response to hypercapnia, L/min/per ΔPa_{CO_2} mm Hg	>1.5

Pulmonary Hemodynamics

Pulmonary blood flow (cardiac output), L/min	5.4
Pulmonary artery systolic/diastolic pressure, mm Hg	25/8
Pulmonary capillary blood volume, mL	100
Pulmonary “capillary” (wedge) blood pressure, mm Hg	<10
